PURPOSE

To assess interval cancer rate in a large, prospective digital breast tomosynthesis (DBT) screening trial in comparison with a concurrent screening population and to assess tumor characteristics of interval cancers in DBT-screening.

METHOD AND MATERIALS

The prospective ****Trial, comparing digital breast tomosynthesis (DBT) with digital mammography (DM) in 14,848 women has shown a significantly increased sensitivity with DBT. Interval cancer rate in the trial was compared with a concurrent screening population; i.e. women participating in DM screening at the same screening site during the same time period (2010-15, n=100,273 screens). Interval cancers and concurrent screens were identified through linkage with the Radiology Information System, the **Cancer Registry and the National Quality Register Breast Cancer. Confidence intervals (CI) 95 % were calculated for rates and difference between rates. Tumor characteristics were retrieved from pathology reports and invasive cancers classified according to St Gallen subtypes.

RESULTS

In total, there were 22 interval cancers in the ****Trial. The interval cancer rate was 1.5 per 1000 screens [22/14,848] (95% CI 0.9-2.2) in the ****Trial and 1.8 per 1000 screens [179/100,273] (95% CI 1.5-2.1) in the concurrent population. Although the interval cancer rate was lower in the trial, the difference of 0.3 was not statistically significant (95 % CI -0.5-0.9). Among the interval cancers in the ****Trial, the mean cancer size was 17 mm (range 2-37 mm), 2 were DCIS (grade 2 and 3), 5 luminal A-like, 9 luminal B-like HER2-, 2 luminal B-like HER2+ and 4 triple negative.

CONCLUSION

The slightly lower interval cancer rate in the trial might indicate that DBT-screening leads to the detection of clinically relevant cancers. Still, a relatively large proportion of the interval cancers had unfavorable prognostic characteristics.

CLINICAL RELEVANCE/APPLICATION

Analysis of interval cancers is important in order to elucidate the future value of DBT in screening.

SSA01-02 Does Tomosynthesis Work For Everyone?

Sunday, Nov. 25 10:55AM - 11:05AM Room: E450A

PURPOSE

To compare the performance of full-field digital screening mammograms (FFDM) with and without digital breast tomosynthesis (DBT) in women with and without breast implants.

METHOD AND MATERIALS

An IRB-approved, HIPAA-compliant retrospective review was performed of 103,070 consecutive screening mammograms obtained from February 2011 through June 2014. Recall rates (RRs), cancer detection rates (CDRs), and positive predictive values for recall (PPV1s) were analyzed.

RESULTS

The following data compare FFDM and FFDM-DBT: 67,331 FFDM and 28,835 FFDM-DBT from women *without* implants yielded RRs of 8.0% and 6.3%, respectively ($p<0.00001$); CDRs of 4.1 and 5.0 per 1000 exams, respectively ($p=0.07$); and PPV1s of 5.1% and 8.0%, respectively ($p<0.0001$). 4325 FFDM and 2579 FFDM-DBT from women *with* implants yielded RRs of 5.2% and 4.1%, respectively ($p=0.040$); CDRs of 1.8 and 2.7 per 1000 exams, respectively ($p=0.46$); and PPV1s of 3.6% and 6.7%, respectively ($p=0.25$). The same data is also used to evaluate the effect of implants on screening: 67,331 FFDM *without* implants and 4325 FFDM *with* implants yielded RRs of 8.0% and 5.2%, respectively ($p<0.00001$); CDRs of 4.1 and 1.8 per 1000 exams, respectively ($p<0.00001$); and PPV1s of 5.1% and 3.6%, respectively ($p=0.30$). 28,835 FFDM-DBT *without* implants and 2579 FFDM-DBT *with* implants yielded RRs of 6.3 and 4.1, respectively ($p<0.00001$); CDRs of 5.0 and 2.7, respectively ($p=0.11$); and PPV1s of 8.0 and 6.7, respectively ($p=0.63$).

CONCLUSION

Tomosynthesis improves the performance of digital screening mammography, while the presence of implants reduces its performance. Specifically, tomosynthesis improved RRs, CDRs, and PPV1s for all women (*with* and *without* implants), though statistically significant differences were seen only for RRs in women *without* implants, RRs in women *with* implants, and PPV1s for women *without* implants. Implants were associated with decreased RRs, worse CDRs, and worse PPV1s for all screening exams (FFDM and FFDM-DBT), but statistically significant differences were seen only for RRs for all screening exams and CDR for FFDM. Further study with larger populations is warranted.

CLINICAL RELEVANCE/APPLICATION

The benefit of tomosynthesis has been incompletely studied in screening mammography patients with implants. This research suggests that tomosynthesis is useful for screening women *with* implants in addition to those *without* implants.

SSA01-03 Disparities in Screening Mammography Cost-Sharing and Utilization Before and After the Affordable Care Act (ACA) and the Revised USPSTF Guidelines

PURPOSE

To assess changes in screening mammography cost-sharing and utilization before and after the Affordable Care Act (ACA) and the revised USPSTF guidelines by race and income level.

METHOD AND MATERIALS

We used patient-level analytic files between 2004 and 2014 from Optum™ Clinformatics™ Data Mart. We included women 40-74 years 1) without a history of breast cancer or mastectomy with 2) at least one year of continuous enrollment in a given plan, examining out-of-pocket payments and utilization for screening mammography. Trends for screening mammography utilization and cost sharing elimination over time by race and income level were visually inspected. We then specifically calculated the slopes and compared trends before and after 2009 and 2010 to assess the impact of ACA implementation and USPSTF guideline revisions on screening mammography cost sharing elimination and utilization.

RESULTS

We identified an average of 2,173,686 commercially insured women ages 40-74 years with at least 12 months of continuous enrollment in a given plan per year. Overall, an upward trend was seen in the proportion of women with zero cost sharing over time among all races and income level. Comparing trends for cost-sharing elimination before and after 2010, a statistically significant upward but small trend was found among all races and income levels with no racial or income disparities evident. Screening mammography utilization plateaued or showed a significant decline after 2009 in all income and racial groups except for African Americans in whom screening rates continued to increase after 2009.

CONCLUSION

Impact of ACA cost-sharing elimination did not differ among various racial and income groups. Among our population of employer-based insured women, the racial gap in screening mammography appeared to have closed and potentially reversed among African American women.

CLINICAL RELEVANCE/APPLICATION

It is important to continue monitoring screening mammography utilization as health care policies and guidelines change, as these changes may affect disparities in screening between different racial and income groups.

SSA01-04 Screening Mammography: There is Value in Screening Women Aged 75 and Over

Sunday, Nov. 25 11:15AM - 11:25AM Room: E450A

Participants
Stamatia V. Destounis, MD, Scottsville, NY (*Presenter*) Research Grant, Hologic, Inc; Research Grant, Delphinus Medical Technologies, Inc

sdestounis@ewbc.com

PURPOSE

To review outcomes of screening mammography performed in women 75 and over to determine the rate of cancer diagnosed and associated histology and surgical excision performed.

METHOD AND MATERIALS

Patients 75 years of age and over who presented for screening mammography and underwent biopsy with resultant malignant pathology were retrospectively collected and analyzed to record patient demographics, lesion information, pathology results and treatment. Cases of non-breast malignancy, cases of breast cancer diagnosed by modality other than mammography, and cases with missing or incomplete records were excluded.

RESULTS

From 2007-2016 there were a total of 679,168 screening appointments, with 3,480 patients diagnosed with screen-detected cancers (5.1/1000). 68,218 (10%) screenings were performed in women aged 75 and over; 530 of these women were diagnosed with 560 breast cancers, for a cancer detection rate of 7.8/1000. Average patient age 80.3 (range 75-98). Lesions most frequently presented as a mass (74%). A large majority (81%) of the malignancies diagnosed were invasive; 55.7% grade 2 or 3. Positive lymph nodes were reported at surgical excision in 7.0% of patients. Tumor stage was largely stage 0 or 1 (64%); 12% were determined to be stage II or III. 98% of cancers were surgically excised; twelve cancers were not due to advanced patient age or overall degraded patient health.

CONCLUSION

For the relatively small percentage of our screening population that women 75 and over comprise (10%), the patients diagnosed in this population made up 16% of all patients diagnosed with screen-detected cancers, a substantial cancer detection rate (7.8/1000). Most of the cancers diagnosed were low grade, a significant number were invasive (81%), over half were grade 2 or 3, and a majority were lower stage (0 or I). Most (98%) underwent surgical excision, suggesting that most women 75 and over are in good health and want to pursue surgical excision. Screening mammography should be performed in this age group given the incidence of breast cancer that exists.

CLINICAL RELEVANCE/APPLICATION

Ongoing debate exists regarding the age to cease screening mammography, citing lack of research in the aging population. Our study demonstrates the value of screening women 75 and over.

SSA01-05 Risk of Breast Cancer After a False-Positive Screening Mammogram in Relation to Mammographic Abnormality: Potential for Prevention?

Sunday, Nov. 25 11:25AM - 11:35AM Room: E450A

rrajapak@bccancer.bc.ca

PURPOSE

False positive recall rates have consistently been identified as a harm of organized breast cancer screening. The extent to which these recalled women are at increased risk of future breast cancer remains unclear.

METHOD AND MATERIALS

All women who had two or more screening mammograms between 1988-2013 in a large organized breast screening program were included in the study. They were followed until a breast cancer diagnosis, last screen date +5 years, or end of follow-up on Dec 31, 2013, whichever came first. The relative risk (RR) of breast cancer for women with a false-positive test compared with women with negative tests was estimated with Poisson regression, adjusted for age, and five calendar periods.

RESULTS

A total of 772,289 women with 4.82 million screening mammograms and a median follow up of 11.8 years were included. There were 238,860 women with false positive findings and 26,950 cancers of which 16,084 screen detected and 10,866 non screen detected. The adjusted RR [Value (95% CI)] of breast cancer after the first false-positive test was 1.73(1.68-1.77) for all, 1.65(1.61-1.70) for invasive, and 2.13(2.01-2.27) for in situ cancers respectively. The RR remained increased beyond 8 years after the first false-positive test. Of the 5157 screen detected cancers after the first false positive test, 3358 (65%) were on the ipsilateral breast while 1799 (35%) were on the contralateral breast. Women with breast density >50% at the time of false positive test had a twofold risk of breast cancer; RR 2.07(1.99-2.14) while those with breast density <50% had a RR of 1.58(1.54-1.63). When stratified for mammographic features found on the first false positive mammogram, architectural distortion plus mass had the highest RR 4.68(3.16-6.93) for invasive cancers while calcifications alone and calcifications plus asymmetry had highest RR 5.57(4.88-6.36) and 4.07(2.49-6.66) for in situ cancers. These findings would require further validation.

CONCLUSION

False positive mammogram correlates with an increased risk of developing breast cancer. Screen detected breast cancers post false positive mammogram most likely to occur in the ipsilateral breast.

CLINICAL RELEVANCE/APPLICATION

Mammographic features at the time of recall predict the risk of subsequent cancer and may warrant increased surveillance and/or chemo-prevention.

SSA01-06 Stratification of Ductal Carcinoma in Situ in a Screening Population by Age and Grade Over a 16-Year Period

asie@memorialcare.org

PURPOSE

To determine if there is a correlation between age and grade of screening-detected ductal carcinoma in situ (DCIS).

METHOD AND MATERIALS

We performed an IRB approved, retrospective review of screening-detected cases of DCIS at our large, community-based breast center, diagnosed between 2001 and 2016. All cases of DCIS diagnosed from 2001 through 2016 were collated. Odds ratios were produced from logistic regression analyses.

RESULTS

DCIS accounted for 20.9% (372/1781) of all cancers detected in our screening practice between 2001 and 2016.The total number of cases in our study was 372, with a mean age of 60.6 years, median age of 60.0 years, mean size of 2.1 cm, median size of 1.8 cm. Age distribution showed 31.7% (118/372) were <55 years old, and 68.3% (254/372) were >= 55 years old. The tumor grade was identified in 366 (98.4%) of the cases and included 6.8% (25/366) low grade, 46.4% (170/366) intermediate grade, and 46.7% (171/366) high grade. Mammographic findings were 80.9 % (301/372) calcifications and 16.9% (63/372) mass or focal asymmetry. Estrogen receptor (ER)/Progesterone receptor (PR) status was identified in 240 (64.5%) cases and included 81.3% (195/240) ER + and 72.9% (175/240) PR+ cases. Logistic regression analysis revealed that for each unit decrease in age, the odds ratio of intermediate versus low grade was 4 times higher (p=0.038), and high versus low grade was 5 times higher (p=0.009). No patient (0/19) under 45 years old had low grade DCIS. Younger women were slightly more likely to have DCIS that was ER+ and PR+.

CONCLUSION

The vast majority of screening-detected DCIS cases (93.1%) were intermediate or high grade. Younger patients had a statistically significant greater chance of intermediate or high grade DCIS versus low grade DCIS.

CLINICAL RELEVANCE/APPLICATION

Grade and age have an inverse relationship in the screening-detected DCIS at our institution during the 16 year period studied. Since screening- detected DCIS in younger patients tends to be high or intermediate grade, screening mammography in younger

patients remains clinically important.

SSA01-07 Frequency and Cancer Yield of Probably Benign Breast Findings in Clinical Practice in the National Mammography Database (BI-RADS Category 3)

Sunday, Nov. 25 11:45AM - 11:55AM Room: E450A

PURPOSE

The Breast Imaging Reporting and Data System (BI-RADS) assessment category 3 describes a probably benign finding with a low likelihood of malignancy of <= 2%. Since 2013, the BI-RADS Atlas discouraged its use at screening, which was reinforced in Medicare's pay-for-performance Physician Quality Reporting System (PQRS) initiative. However, there are sparse data on the frequency of use and cancer yield of BI-RADS 3 findings in clinical practice. This study assesses the frequency and cancer yield of probably benign findings in screening and diagnostic mammography in the National Mammography Database (NMD), which is the largest national database of mammography.

METHOD AND MATERIALS

This HIPAA-compliant and IRB-exempt study retrospectively analyzed data from screening and diagnostic mammograms performed between 1/1/2009 and 12/31/2015 in the NMD. We calculated the overall frequency and cancer yield of BI-RADS 3 findings in screening and diagnostic mammography. Cancer yield is defined as the number of breast cancers diagnosed among women with probably benign findings within the study period. Exams with BI-RADS 3 findings but lacking biopsy or 12-month follow-up were excluded . Exams from NMD facilities contributing data for < 2 years were excluded to ensure adequate follow-up.

RESULTS

Data from 6,421,365 screening and 1,264,929 diagnostic mammograms performed in 3,345,013 women at 261 NMD facilities in 31 states were analyzed. A total of 215,403 mammograms had probably benign findings, with frequency of 0.3% (20,060/6,421,365) in screening and 15% (193,850 /1, 264,929) in diagnostic mammograms. Among the 101,025 women with BI-RADS 3 findings and at least one follow up , 948 (0.94%, 95%CI 0.91, 1.03) women had a diagnosis of malignancy. Rates of BI-RADS 3 use were stable over the 6 calendar years analyzed.

CONCLUSION

A probably benign, BI-RADS 3, assessment was rarely used in screening but common in diagnostic mammography in the NMD. The overall cancer yield of probably benign findings was 0.94%, consistent with BI-RADS Atlas threshold of <= 2%. These results support use of probably benign assessment in clinical practice for findings with low risk of malignancy.

CLINICAL RELEVANCE/APPLICATION

In the NMD, BI-RADS 3 showed appropriately low cancer yield of 0.9%. Proper use of BI-RADS 3 helps reduce cost, morbidity and patient anxiety while increasing cost-effectiveness of screening.

SSA01-08 Digital Breast Tomosynthesis Improves Performance Metrics of Screening Mammogram in Women Aged 40 to 54 Compared to Full Field Digital Mammogram

Sunday, Nov. 25 11:55AM - 12:05PM Room: E450A

amir.imanzadeh@yale.edu

PURPOSE

The starting age for screening mammogram has been a controversial subject mostly due to reported low cancer detection rate (CDR) and high false positive recall rate (RR) in younger women. However, digital breast tomosynthesis (DBT) may improve performance of screening mammogram and change the justification of screening guidelines. The purpose of this study is to compare the performance of screening mammogram in women aged 40-54 between full field digital mammogram (FFDM) and DBT.

METHOD AND MATERIALS

In an IRB approved study, we retrospectively analyzed screening mammograms performed in women aged 40-54 at 2 of our imaging

centers from August 2008 through April 2017. We included all FFDM screening mammograms performed before and all DBT screenings performed after installation of DBT at each site. DBT screening was offered to all women after installation at no additional charge. RR, CDR, and characteristics of screen-detected cancers were compared between FFDM and DBT screening in 3 age groups: 40-44 (group 1), 45-49 (group 2) and 50-54 (group 3).

RESULTS

16938 FFDM and 28313 DBT were performed in women aged 40-54. In FFDM, RR significantly decreased from group 1 (17.4%) to group 2 (14.0%) and group 3 (11.3%); however, in DBT screening, RR was only significantly decreased from group 1 (12.2%) to group 2 (9.1%) and there was no significant difference between group 2 and group 3 (8.4%). RR of all 3 age groups were significantly lower for DBT compared to FFDM. CDR per 1000 exams in FFDM was significantly lower in groups 1 and 2 (2.4 and 2.3) compared to group 3 (5.0), but in DBT, there was no significant difference in CDR among the 3 groups (3.0, 4.4, and 3.8 in groups 1,2, and 3, respectively). There was significant increase in CDR from FFDM to DBT in women aged 45-49 (p=0.03). The ratio of invasive to in-situ carcinomas were similar in FFDM and DBT subgroups.

CONCLUSION

DBT screening decreases RR and increases CDR compared to FFDM in women aged 40-49, and more prominently for 45-49 age group. As a result, unlike FFDM, there is no significant difference in RR and CDR of ages 45-49 and 50-54 with DBT screening.

CLINICAL RELEVANCE/APPLICATION

Improved performance of DBT screening in women aged 40-49 compared to FFDM screening, may further justify recommendations for starting screening mammogram at younger age.

SSA01-09 Six Years of Consecutive, Population-Based Screening with Digital Breast Tomosynthesis: Outcomes by Screening Year and by Screening Round

PURPOSE

Digital breast tomosynthesis (DBT) improves screening outcomes by decreasing recalls and increasing cancer detection. However, most DBT studies have analyzed prevalence rather than incidence screening. We investigate outcomes from 6 years of consecutive DBT screening, at both the population level by year (DBT Y1-6) and patient level by round (DBT R1-6).

METHOD AND MATERIALS

71535 consecutive DBT screens in 33245 women were performed from 10/2011 to 9/2017 with 31246, 17801, 11067, 6560, 3553, and 1308 screens in rounds 1-6, respectively. Recall rate % (RR), cancer detection (CDR), biopsy (BX) and false negative (FN) rates per 1000 screens for each year (DBTY1-Y6) and each round (R1-R6) were analyzed. Outcomes were compared the prior year of digital mammography (DM) screening (DMY0, n=10765). Cancer registry data was used to determine FN (defined as cancer diagnosed <1 yr after negative screen) for DMY0-DBTY5 and DBT R1-R5.

RESULTS

At the Population Level, RR for DBTY1-6 was lower than DMY0 (7.9 vs 10.4%). However, DBT RR increased in DBTY1-3 (8.8, 9.0, 9.2%) before decreasing in DBTY4-6 (7.1, 6.1, 7.4%). CDR increased in DBTY1-3 (5.5, 5.8, 6.5) then decreased in DBTY4-6 (6.3, 5.1, 5.5) however, DBT CDR was higher in each year than DMY0 (4.8). Invasive CDR for DBTY1-4 and DBTY6 (3.9, 4.5, 4.5, 4.9, respectively) were also higher than DM0 (3.4) however, DBTY5 was lower (2.9). BX increased from DMY0 of 1.9 to 2.2, 1.9, 2.0 in DBTY1-3; in DBTY4-6, BX rates were lower (1.5, 1.3, 1.5). FN remained without significant change from DMY0 (1.1) to DBT1-5 (0.5, 0.3, 0.4, 0.8, 1.0). By Screening Round, RR decreased from DBTR1 to R5 from 10.6, 7.0, 5.1, 4.5, 4.1 until R6= 4.2%. CDR for R1-6 were 6.4, 5.5, 6.1, 4.4, 4.2, 3.1, respectively. BX rate decreased after DBTR1 (2.5) for R2-6 (1.4, 1.4, 1.0, 0.8, 1.0). FN were 0.5, 0.5, 1.3, 0.6, 0.8 for R1-5. Whether by year or round, DBT PPV1 was higher than DM.

CONCLUSION

At the population level, DBT screening had higher overall CDR and lower RR than DM with FN rates remaining relatively stable. Little data exists on outcomes by round of screening, however, our data may help guide DBT screening benchmarks.

CLINICAL RELEVANCE/APPLICATION

Consecutive years of DBT screening show decreased recall and increased PPV1 compared to DM alone. Further long term DBT outcome data may help guide new, personalized screening algorithms by age, density and risk.

PURPOSE

To assess the extent of background parenchymal enhancement (BPE) at contrast-enhanced spectral mammography (CESM), inter-reader agreement in BPE classification, and correlation between BPE and breast cancer.

METHOD AND MATERIALS

Between 2012 and 2015 a total of 516 women underwent CESM imaging for screening and diagnostic purposes. BPE on CESM images was retrospectively, independently and blindly graded by 4 reviewers using the following scale: minimal, mild, moderate or marked. Inter-reader agreement was estimated using correlation coefficient (ICC). Associations between BPE and clinical factors, biopsy rate and histopathology results were examined using a multivariate logistic regression analysis.

RESULTS

A total of 412 (80%) of women underwent CESM for screening purposes. Mean age was 53 (range 28-77) years and 86.2-94% had a breast density BI-RADS score of C-D. Most women (76.4-90.5%) had minimal or mild BPE at CESM. Overall inter-reader agreement on BPE scores was good (ICC 0.88, 95%CI 0.81-0.92). A total of 122 (24%) biopsies were performed with a malignant histopathology result in 45 (37%) cases. On a multivariate analysis BPE demonstrated a significant association with age (P=0.004, OR 0.942, 95%CI 0.905-0.981) and with biopsy performance rate (P=0.006, OR 2.646, 95%CI 1.319-5.307). Moderate or marked BPE was predictive of a malignant biopsy result (P=0.002, OR 3.105, 95%CI 1.541-6.259).

CONCLUSION

CESM BPE is correlated with age and biopsy rate. Moderate or marked BPE is associated with malignant biopsy results, and hence may predict an increased risk for breast cancer.

CLINICAL RELEVANCE/APPLICATION

CESM BPE grading may be used as an additional risk assessment tool for breast cancer.

SSA02-02 Contrast Enhanced Digital Mammography (CEDM) Helps to Safely Reduce Benign Breast Biopsies

PURPOSE

One criticism of breast imaging is the harm caused by the relatively high rate of biopsy of benign breast lesions -- particularly BIRADS 4A and 4B lesions. The purpose of this project is to assess if CEDM during diagnostic evaluation could increase biopsy PPV for soft tissue density lesions by reducing benign biopsies while not impacting biopsy of cancers.

METHOD AND MATERIALS

This HIPPA compliant IRB approved protocol accrued 57 consenting women aged 34-74 (avg 49) years with 60 BIRADS 4A or 4B soft tissue lesions scheduled for ultrasound (US), stereotactic or tomosynthesis (DBT) directed biopsy from April 2016-November 2017. CEDM was performed immediately prior to biopsy. The cohort included 46 masses, 6 asymmetries and 8 distortions. Pathology confirmed 9 cancers and 51 benign concordant lesions. Four MQSA qualified radiologists reviewed and provided a BIRADS score 3 times for each lesion: first for mammography (M)/DBT only, next with US added and third with CEDM added. Readers recorded if the lesion enhanced, how enhancement compared to background and background parenchymal enhancement. Differences in BIRADS ratings were compared.

RESULTS

After M/DBT and US, prior to CEDM, 173/240 (72%) ratings were classified as > BIRADS 4. After viewing CEDM, 60 of these were re-classified as < BIRADS 3; a 35% average [range 0-59%] reduction in biopsy recommendation ($p<0.05$). Cancers enhanced in 32/36 (89%) ratings and 32/36 cancers were rated as BIRADS >4 before and after CEDM. Benign lesions enhanced in 77/204 (38%) (false positives). With US 3/36 cancer and 44/204 benign were converted to BIRADS>4 and 2/36 cancer and 10/204 benign to BIRADS <3 rating. With CEDM, 1/36 cancer and 8/204 benign were converted to BIRADS>4 and 1/36 cancer and 60/204 benign to BIRADS<3. Hence 1/36 cancer ratings (2.7%) were adversely affected (false negative) by CEDM.

CONCLUSION

CEDM use during diagnostic evaluation of BIRADS 4A or 4B lesions may result in a significant increase in PPV with minimal impact on cancer diagnosis rates.

CLINICAL RELEVANCE/APPLICATION

CEDM use during diagnostic evaluation of BIRADS 4A or 4B soft tissue lesions may significantly reduce the number of women recommended for benign biopsy while missing very few cancers.

SSA02-03 Diagnostic Performance of Contrast-Enhanced Spectral Mammography for Suspicious Malignant Microcalcifications (BI-RADS 4)

Sunday, Nov. 25 11:05AM - 11:15AM Room: E450B

For information about this presentation, contact:

lucky_6677@126.com

PURPOSE

To assess the diagnostic performance of contrast-enhanced spectral mammography (CESM) for evaluation of suspicious malignant microcalcifications (BI-RADS 4) comparing with full-field digital mammography (FFDM).

METHOD AND MATERIALS

Patients with mammographic calcifications without associated mass or distortions and were originally reported as BI-RADS 4 during Jan 2015 to Jan 2018 were retrospectively collected. Lesions that proven through pathological diagnosis either by biopsy or operation were included in the study and grouped as FFDM or CESM according to the examination they received. The microcalcification morphology and associated enhancement (CESM group) were reviewed by two radiologists to analyse the accuracy of the diagnosis . Diagnostic accuracy was assessed respectively for FFDM and CESM versus the results of pathology. Statistical differences of the two methods were compared using Chi-square test.

RESULTS

48 lesions (13 malignant and 35 benign) from 48 patients were enrolled in FFDM group, and 31 lesions (10 malignant and 21 benign) from 30 patients were in CESM group. The diagnostic sensitivity, specificity, positive predictive value, negative predictive value and accuracy were 92.3%, 42.9%, 37.5%, 93.8%and 56.3% for FFDM group, and were 100%, 71.4%, 62.5%, 100% and 80.6% for CESM group, respectively. The specificity and accuracy of CESM were significantly higher than that of FFDM ($p<0.05$). All 10 cancers including 8 DCIS in CESM group were judged as enhancement (table 1).

CONCLUSION

Comparing with FFDM, CESM improve the diagnostic performance on BI-RADS 4 mammographic calcifications, especially on specificity and overall accuracy. The detectability of all DCIS lesions in this small cohort may validate its potential use in previously "calcification only" disease, but still need further large sample to confirm.

CLINICAL RELEVANCE/APPLICATION

CESM improve the diagnostic performance on BI-RADS 4 mammographic calcifications, and decrease unnecessary biopsies.

SSA02-04 Participants

Quantitative Objective Evaluation of Contrast-Enhanced Spectral Mammogram in Predicting Response to Neo-Adjuvant Chemotherapy: A Comparative Study with RECIST 1.1 and Combined Evaluation Methods

PURPOSE

Initiating a new objective quantitative tool for evaluation of residual disease after neoadjuvant chemotherapy using CESM in comparison to RECIST 1.1 and combind evaluation methods.

METHOD AND MATERIALS

The study was approved by the ethical commitee of a multidisciplinary breast cancer hospital. It included 42 patients scheduled for receiving NAC. They underwent 2 CESM examinations; prior to and after NAC and maximum10 days prior to surgery. All patients were assessed using the RECIST 1.1 criteria, a combined approach (RECIST+ qualitative subjective assessment) and a new quantitaive approach using an image analysis software (MATLAB and Simulink, Release 2013b). The technique consists of 3 main steps: 1-preprocessing 2. extracting the region of Interest (ROI) and 3- Assessing the response to chemotherapy depending on the analysis of the tumour number of pixels included within the ROI. The difference in the intensity of enhancmenet between the pre and post NAC enahncement is calculated and compared between the 3 assessment methods in correlation to postoperative pathology using the Miller-Payne grading. For statistical evaluation, patients were classified into responders and non-responders.

RESULTS

The calculated correlation coefficient when comparing the residual disease on CESM and Miller payne grade using RECIST 1.1, the combined approach and the proposd quantitative method was 0.59, 0.89 and 0.69 respectively. According to Miller Payne grading 39/42 cases were classified as responders (Miller payne III, IV, and V). Using the new quantitive approach all 39/39 cases (100%) were considered responders in comparison to 38/39 using the combined approach and 34/39 using the RECIST 1.1 criteria. The calculated sensitivity, positive and negative predictive values of the quantitative objective evaluation (100, 97.5,100 % respectively) was higher than the RECIST method (87.2%, 97.1% 28.6%) and the combined response method (97.4%,97.4% and 66.7%).

CONCLUSION

Quantitative objective analysis of CESM allows accurate objective evaluation of the response of breast cancer to chemotherapy and evaluation of residual tumor prior to surgery.

CLINICAL RELEVANCE/APPLICATION

Objective analysis of CESM is an accurate tool for evaluation of the response of breast cancer post neo-adjuvant chemotherapy and is recommended as part of pre-operative work up

SSA02-05 Diagnostic Value of Contrast-Enhanced Spectral Mammography in Comparison to MRI in a Population of Breast Lesions

Sunday, Nov. 25 11:25AM - 11:35AM Room: E450B

Participants
Dong Xing, MBBS, Yantai, China (*Abstract Co-Author*) Nothing to Disclose
Xiaoxiao Chi I, Yantai, China (*Presenter*) Nothing to Disclose

Haizhu Xie, Yantai, China (*Abstract Co-Author*) Nothing to Disclose
Amiee Chen, Shanghai, China (*Abstract Co-Author*) Nothing to Disclose
Huizhi Cao, PhD, Beijing, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic value between contrast-enhanced spectral mammography (CESM) and breast magnetic resonance imaging (MRI).

METHOD AND MATERIALS

Between July 2017 and February 2018, 235 patients who were suspected of breast abnormalities by clinical examination or mammography were underwent CESM and MRI examination. The image of CESM and MRI and the pathological specimens were analyzed. All lesions were evaluated independently by three experienced radiologists. Using histopathological results as the gold standard, the diagnostic performance of CESM and MRI were investigated. The areas under ROC curves was applied to analyze diagnostic efficiency. The data on maximum tumor size measurements were gathered on CESM and MRI. The Pearson's correlation coefficients and 95% confidents intervals between CESM vs. pathology and MRI vs. pathology were calculated.

RESULTS

263 breast lesions were found in 235 patients, in which 177 were malignant and 86 were benign. By evaluating the diagnostic value,

the sensitivity, positive prediction value, negative predictive value, and false-negative from CESM examination was comparable to that from MRI (91.5%,94.7%,83.7%,8.5% versus 91.5%,90.5%,82.1%,8.5%). Importantly, the accuracy and the specificity were higher for CESM than that for MRI (81%,89.5% Vs. 80.2%,71.7%) while the the false-positive was lower(10.5% Vs. 19.8%). The areas under ROC curves of CESM and MRI were 0.950 and 0.939, displaying the equivalent diagnostic efficiency (p=0.48). For the agreement between measurements, mean tumor size was 3.1 (range 0-16) cm for CESM and 3.4 (range0-17) cm for MRI compared with 3.2 (range 0-16) cm on histopathological results, the average difference of diameters between CESM, MRI and Histopathologic size was -0.01, -0.05cm, respectively, with 95% consistency interval range of -0.34 to 0.31, -0.87 to 0.22cm, respectively. The Pearson's correlation coefficients of CESM versus histopathology (r=0.774, p=0.000) was consistent with MRI (r=0.771, p=0.000).

CONCLUSION

Our results show better accuracy, specificity and the lower false-positive of CESM in breast cancer detection than MRI. CESM displayed a good correlation with histopathology in assessing the lesion size of breast cancer, which is consistence with MRI.

CLINICAL RELEVANCE/APPLICATION

CESM provides additional enhancement information for diagnosing breast lesions and measuring cancer sizes with high correlation to surgicohistology.

SSA02-06 Usefulness of Low-Dose Perfusion Breast CT: Quantification of Tumor Vascularity and Prediction of Histologic Biomarkers in Invasive Breast Cancer

PURPOSE

To investigate the usefulness of low-dose perfusion breast computed tomography (CT) for quantification of tumor vascularity and for prediction of histologic biomarkers in invasive breast cancer.

METHOD AND MATERIALS

This prospective study was approved by IRB with informed consent. A total of 139 patients with invasive breast cancers were enrolled. Low-dose perfusion CT was performed in the prone position with a spectral CT (iQon, Philips Healthcare) after contrast injection (Xenetix350, Guerbet). Effective dose was less than 1.2 mSv. Perfusion parameters were measured using a Philips Advanced Perfusion and Permeability application prototype in breast cancers, normal breast tissue, and fat; peak enhancement intensity (HU), perfusion on deconvolution model (mL/min/100/g), mean transit time (sec), time to peak (sec), blood volume (mL/100/g), permeability (mL/min/100/g), and blood volume permeability on Patlak model (mL/100/g). CT perfusion parameters of cancers and normal tissue or fat were compared using Mann-Whitney test. Correlation analysis was performed between CT perfusion parameters of cancers and histologic biomarkers including tumor grade, estrogen receptor (ER), progesterone receptor (PR), human epidermal growth factor receptor 2 (HER2), and Ki67 using Mann-Whitney or Kruskal-Wallis test.

RESULTS

In breast cancers, peak enhancement intensity, perfusion, blood volume, permeability, and blood volume permeability were significantly higher, and mean transit time, time to peak were shorter than those values in normal glandular tissues and fat ($P<.001$ for all). Peak enhancement intensity significantly increased in cancers with ER-, PR-, HER2+, Ki67+ or more than 20 mm ($P<.05$ for all). Time to peak decreased in cancers with ER-, PR-, HER2+, Ki67+, high grade, or more than 20 mm ($P<.05$ for all). Blood volume permeability increased in cancers with ER-, PR-, Ki67+, or high grade ($P<.05$ for all). HER2-enriched cancers showed higher peak enhancement intensity and blood volume permeability than luminal type cancers ($P<.02$ for all).

CONCLUSION

Low-dose perfusion breast CT can be useful in quantifying tumor vascularity and predicting prognostic biomarkers of invasive breast cancer.

CLINICAL RELEVANCE/APPLICATION

Low-dose perfusion breast CT can be used to quantify tumor vascularity and to predict biomarkers of invasive breast cancer and for patients who have difficulty with magnetic resonance imaging.

SSA02-07 Contrast-Enhanced Cone-Beam Breast-CT without Prior Non-Contrast Scan: Can We Reduce Radiation Exposure While Maintaining Diagnostic Accuracy?

Sunday, Nov. 25 11:45AM - 11:55AM Room: E450B

Participants
Susanne Wienbeck, MD, Goettingen, Germany (*Presenter*) Nothing to Disclose
Uwe Fischer, MD, Goettingen, Germany (*Abstract Co-Author*) Nothing to Disclose
Joachim Lotz, MD, Gottingen, Germany (*Abstract Co-Author*) Nothing to Disclose
Johannes Uhlig, Goettingen, Germany (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

susanne.wienbeck@med.uni-goettingen.de

PURPOSE

Contrast-enhanced cone-beam breast-CT (CE-CBCT) is a novel breast imaging technique with comparably high radiation dose. The current diagnostic standard includes one non-contrast scan (NC-CBCT) followed by intravenous contrast media injection and a contrast-enhanced scan (CE-CBCT). Performing only the CE-CBCT scan might reduce radiation exposure. Our study aims to evaluate whether CE-CBCT alone is comparable to combined NC + CE-CBCT regarding diagnostic accuracy while reducing radiation exposure.

METHOD AND MATERIALS

This prospective IRB-approved study included 48 women (61 breasts, 100 lesions) with median age 57.9 years (IQR: 49-66 years) and BI-RADS 4/5 lesions diagnosed on mammography/ultrasound in ACR density types c/d breasts. Two blinded breast radiologists read CE-CBCT alone versus NC-CBCT + CE-CBCT in consensus. Intra-observer variability was assessed by one reader performing independent double reading. Sensitivity, specificity and AUC were measured separately for CE-CBCT alone versus NC + CE-CBCT.

RESULTS

Of 100 lesions, 51 were rated as malignant, 6 as high risk and 43 as benign. Histopathological assessment was performed in 63 breast lesions and imaging follow-up over at least 1 year in another 37 lesions. Diagnostic accuracy for both CBCT approaches was comparable: AUC, sensitivity and specificity showed no significant differences comparing CE-CBCT alone versus NC + CE-CBCT (AUC: 0.84 vs. 0.83, p=0.643; sensitivity: 0.89 vs. 0.85, p=0.158; specificity: 0.73 vs. 0.76, p=0.655). Inter- and intra-observer agreement on BI-RADS readings were excellent (ICC=0.76, ICC=0.83, respectively). Radiation dose was significantly lower for CE-CBCT alone versus NC + CE-CBCT (median average glandular radiation dose 5.9 mGy vs. 11.7 mGy, p<0.001).

CONCLUSION

The diagnostic accuracy of CE-CBCT alone is comparable to that of combined NC + CE-CBCT in ACR type c/d breast. At the same time, CE-CBCT significantly reduces radiation exposure to the breast. Further research is warranted to confirm these findings in a larger and generalizable population.

CLINICAL RELEVANCE/APPLICATION

Assessment of CE-CBCT alone yields comparable diagnostic accuracy to combined NC + CE-CBCT and reduces radiation exposure by up to 50%. Additional acquisition of NC-CBCT might therefore be unnecessary.

SSA02-08 Automatic Classification of Breast Lesions in Contrast Mammography Using Deep Learning in Conjunction with Multimodal Information: BIRADS Lexicon Features and Raw Image Features

mirisklair@gmail.com

PURPOSE

To assess the combined usage of BIRADS lexicon and pixel data for multimodal automatic classification of breast lesions in dual energy contrast enhanced spectral mammography (CESM) and evaluate its potential for biopsy sparing in benign breast lesion.

METHOD AND MATERIALS

130 biopsy proven CESM breast lesions, (65 benign and 65 malignant) were manually contoured and described by the BIRADS lexicon. BIRADS data was encoded by a binary vector for each lesion which, together with the lesion pixels, formed a multimodal representation. A deep neural network was designed to process pixel data from its entry layer and merge it with BIRADS data in its deepest layers to better balance between low-level pixel information and high-level BIRADS data that need to be merged. The network was validated in a 5-folds cross-validation (CV) scheme, to tell apart benign/malignant lesions. In each fold, a different subset of 25 lesions was used for testing, and the rest for training. This CV was conducted using 3 different configurations, in order to assess and compare the contributions of different information modalities. (a) BIRADS-only classifier using SVM (BOC), (b) pixel-only network (PON), (c) and the multimodal BIRADS+pixels network (MBPN).

RESULTS

The results are shown in Fig.1, where blue is benign and red is malignant. The classification score (y axis) reflects malignancy probability. We seek a threshold, below which there are only benign lesions, so that no malignancy is missed, i.e. sensitivity=100% (green line Fig.1). With this condition in mind, the maximal specificities (SP) are: (a) BIRADS only, SP=12%; (b) pixel-only network, SP=37%; (c) multimodal BIRADS and pixel network (MBPN), SP=60%. This means that with MBPN we can safely spare unnecessary biopsy for 60% of benign lesions without missing any malignancies.

CONCLUSION

This research showed that the combined usage of BIRADS data, provided by the radiologist, with pixel data extracted from CESM strongly improves the specificity obtained for automatic lesion classification on pixel or BIRADS data alone.

CLINICAL RELEVANCE/APPLICATION

Multimodal lesion classification in CESM may significantly reduce benign breast biopsies, thus reducing cost and improving patient experience.

SSA02-09 Preoperative Diagnosis of Metastatic Axillary Sentinel Lymph Nodes in Breast Cancer with Quantitative Parameters Derived from Dual-Energy Spectral CT

Sunday, Nov. 25 12:05PM - 12:15PM Room: E450B

Participants
Chushan Zheng, Guangzhou, China (*Presenter*) Nothing to Disclose
Xiang Zhang, Guangzhou, China (*Abstract Co-Author*) Nothing to Disclose
Jun Shen, MD, Guagnzhou, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

The purpose of this study was to evaluate the diagnostic performance of gemstone spectral imaging (GSI) quantitative parameters derived from dual-energy spectral computed tomography (DEsCT) for the preoperative diagnosis of metastatic sentinel lymph nodes (SLNs) in patients with breast cancer.

METHOD AND MATERIALS

This prospective study was approved by the ethics committee, and all patients provided written informed consent. From June 2015 to December 2017, dual-phasic contrast-enhanced DEsCT was performed in 193 female patients with breast cancer. Quantitative GSI and morphological parameters were compared between metastatic and non-metastatic SLNs. The quantitative parameters were fitted to univariate and multiple logistic regression models. Their diagnostic abilities were analyzed by receiver operating characteristic curves and compared by the McNemar test.

CONCLUSION

DEsCT can be used as a complementary means for the preoperative identification of SLN metastases in patients with breast cancer.

CLINICAL RELEVANCE/APPLICATION

The slope of the Hounsfield unit curve in venous phase derived from dual-energy spectral CT, can be used to differentiate metastatic from non-metastatic axillary sentinel lymph nodes of breast cancer.

PURPOSE

Low baseline ESS promotes development of high-risk plaque features. High ESS in one CTA-based hyperemic simulation technology (Heartflow FFRCT) was also recently shown to predict invasive FFR<=0.8. We determined the relationship of resting to hyperemic ESS using non-proprietary CTA-based rest/stress simulation algorithms, and whether flow state affects the ability of ESS to predict FFR<=0.8. Neither of these relationships have been previously assessed for data derived entirely from CTA.

METHOD AND MATERIALS

Computational fluid dynamics (CFD) was performed for 63 adults from CTA prior (<90d) to invasive FFR. Rest-state CFD used only CTA data (myocardial mass, Murray's law). Stress CFD coupled the epicardial arteries to a microvascular resistance model using 1/4 the resistance values obtained by the rest CFD. Only commercial CTA segmentation and CFD software was used. Rest and stress ESS at relevant locations (eg, coronary segments, across lesion, min lumen diameter, every 3 mm, min/max ESS) were compared (t-test) between FFR<=0.8 vs >0.8 vessels. Receiver operating characteristic area-under-the-curve (AUC) to predict FFR<=0.8 in all vessels was compared for diameter stenosis (%DS) and plaque volume (%PV) by CTA, CT-FFR, and rest and stress ESS.

RESULTS

In vessels where CT-FFR differed <0.05 from FFR (ie, stress CFD matched the patient's true hyperemic conditions), most ESS metrics differed significantly for FFR<=0.8 vs >0.8 vessels, eg lesion rest ESS=4.2 vs 1.9 Pa (p=0.012) and stress ESS=17.0 vs 9.6 (p=0.001), or, maximum ESS (rest: 9.5 vs 4.1, p=0.001; stress: 37.0 vs 19.6, p<0.001). Notably, the minimum ESS did not differ for FFR<=0.8 vs >0.8 vessels (rest p=0.184, stress p=0.454), but the location of minimum ESS differed in 31 of 40 vessels between rest and stress. AUC to detect FFR<=0.8 was 0.57 for CTA %DS, 0.74 for %PV, 0.9 for CT-FFR, and 0.86 for rest and 0.85 for stress ESS across the lesion. The AUC of rest and stress ESS was not inferior to that of CT-FFR (p=0.446); CT-FFR statistically significantly improved only upon the AUC of %PV.

CONCLUSION

High ESS across a lesion at either baseline or hyperemia is associated with lesion-specific ischemia, and both have similar diagnostic accuracy as CT-FFR to detect FFR<=0.8. Low ESS regions differ between rest and stress.

CLINICAL RELEVANCE/APPLICATION

ESS from CTA can detect lesion-specific ischemia similarly to CT-FFR, with or without the need to simulate hyperemia.

PURPOSE

The PERFECTION study is a longitudinal, prospective and consecutive cohort study to compare the feasibility and accuracy of FFRCT versus stress-CTP for the diagnosis of functionally significant CAD.

METHOD AND MATERIALS

One-hundred-forty-seven consecutive symptomatic patients (Mean age: 65.8±9.2; Male: 105) for chest pain who were referred for non-emergent, clinically indicated ICA plus invasive FFR were enrolled. The primary endpoint was to compare the diagnostic accuracy of cCTA versus cCTA+FFRCT versus cCTA+stress-CTP for the detection of significant CAD in a vessel and patients-based analysis defined by ICA with an invasive FFR <= 0.80 or coronary artery stenoses >= 80% or totally occluded vessels.

RESULTS

Rest cCTA was successfully performed in all patients, FFRCT was performed in 143 out of 147 patients and stress-CTP was performed in 144 out of 147 patients. cCTA demonstrated a vessel and patient-based sensitivity (SE), specificity (SP), negative predictive value (NPV), positive predictive value (PPV) and diagnostic accuracy (ACC) of 99%, 76%, 100%, 61%, 82% and 95%, 54%, 94%, 63%, 74%, respectively. The diagnostic performance of integrated protocol of rest cCTA+FFRCT showed a vessel and patient-based SE, SP, NPV, PPV and ACC of 88%, 94%, 95%, 84%, 92% and 90%, 85%, 92%, 83%, 87%, respectively. Finally, the diagnostic performance of integrated protocol of rest cCTA+stress-CTP showed a vessel and patient based SE, SP, NPV, PPV and ACC of 92%, 95%, 97%, 87%, 94% and 98%, 87%, 99%, 86%, 92%, respectively. Both FFRCT and stress-CTP significantly improved SP, PPV and overall ACC in both per-vessel and per-patient based model when added to cCTA, while no differences were found between cCTA+FFRCT versus cCTA+stress CTP.

CONCLUSION

Both FFRCT and stress-CTP are valid tool in addition to cCTA to evaluate the functional relevance of CAD. Based on these results, in patients with suspected CAD, cCTA alone or with integrated FFRCT might be sufficient to exclude relevant stenosis with the advantage to require a single acquisition with a low radiation exposure and low amount of contrast agent. Nevertheless, it might be reasonable to combine stress-CTP data in some patients with positive integrated cCTA+FFRCT exam thanks to the better specificity.

CLINICAL RELEVANCE/APPLICATION

FFRCT and CTP in addition to cCTA can be helpful to evaluate the functional relevance of CAD

SSA03-03 CT Myocardial Perfusion Imaging and CT Angiography-Derived Coronary Fractional Flow Reserve for the Prediction of Major Adverse Cardiac Events in Patients with Coronary Artery Disease

PURPOSE

To determine the prognostic value of dynamic CT perfusion imaging (CTMPI) and CT coronary angiography (CCTA)-derived fractional flow reserve (CT-FFR) for the prediction of major adverse cardiac events (MACE).

METHOD AND MATERIALS

Data was included from four institutions using patients who underwent CCTA and stress dynamic CTMPI on a 3rd generation dual-source CT system with a follow up period of 18 months or until MACE occurred. On-site CT-FFR was computed for each coronary artery. Using CTMPI data, a myocardial blood flow (MBF) index was calculated, for which each vessel territory was normalized to global MBF. The lowest CT-FFR and MBF index was recorded for each patient. The prognostic value of CTA, CT-FFR, MBF index, as well as the combination of the three was evaluated for the prediction of MACE using binary logistic regression and measures of diagnostic accuracy.

RESULTS

Of the 81 total patients included, 25 (31%) experienced MACE during the follow up period. CCTA alone had an area under the curve (AUC) of 0.655 for predicting MACE, with a corresponding sensitivity and specificity of 56% and 75%, respectively. The CT-FFR AUC for the prediction of MACE was 0.703 with a sensitivity and specificity of 64% and 80%, respectively. The optimal threshold computed with the Youden index was 0.75. Dynamic CTMPI had an AUC of 0.812 using the index MBF with a sensitivity and specificity of 88% and 75%, respectively. Using the Youden index, the optimal threshold for index MBF was 0.88. In cases with a negative CTMPI and positive CT-FFR, index MBF was most predictive of outcome (83% of patients). The combination of CCTA, CT-FFR, and CTMPI resulted in an improved AUC of 0.857 compared to CT-FFR and CTMPI alone.

CONCLUSION

Combined CT-FFR and dynamic CTMPI analysis based on cardiac CT imaging is a promising approach for the prediction of MACE in patients with coronary artery disease. While both techniques individually demonstrate good diagnostic accuracy, an integrated approach using both modalities improved the diagnostic accuracy for predicting MACE.

CLINICAL RELEVANCE/APPLICATION

This study shows the benefit of a combined CT-FFR/CTMPI approach to predict MACE. The correct identification of patients at risk of MACE can improve the efficiency and cost-effectiveness of treatment.

SSA03-04 Machine Learning Based CT-FFR Integrating With Quantitative Myocardial Mass Subtended By Coronary Stenosis Outperforms Plaque Features for Predicting Hemodynamical Significance of Lesions

Sunday, Nov. 25 11:15AM - 11:25AM Room: S404AB

Participants
Mengmeng Yu, MA, Shanghai, China (*Presenter*) Nothing to Disclose
Jiayin Zhang, MD, Shanghai, China (*Abstract Co-Author*) Nothing to Disclose

radiologistmoon@163.com

PURPOSE

To study the diagnostic performance of the ratio of subtended myocardial mass to the minimal lumen diameter (MLD) at coronary computed tomographic angiography (CCTA) and machine learning based CT-FFR for differentiating functionally significant from insignificant lesions, with reference to fractional flow reserve (FFR).

METHOD AND MATERIALS

Patients who underwent both coronary CTA and FFR measurement at invasive coronary angiography (ICA) within 2 weeks were retrospectively included in our study. CT-FFR, subtended myocardial mass (V sub), percentage of V sub, V ratio/MLD, along with other parameters, including minimal luminal area (MLA), MLD, lesion length (LL), diameter stenosis, area stenosis, plaque burden, and remodeling index, low attenuation plaque, napkin-ring sign, spotty calcification of lesions were recorded. Lesions with FFR <= 0.8 were considered to be functionally significant.

RESULTS

One hundred and seventy-two patients with 196 lesions were ultimately included for analysis. The LL, diameter stenosis, area stenosis, plaque burden, V sub , V ratio and V ratio/MLD were all significantly longer or larger in the group of FFR <= 0.8 ($p < 0.001$ for all), while smaller MLA, MLD and CT-FFR value were also noted ($p < 0.001$ for all). There were no significant differences between the hemodynamic significant subgroup and insignificant subgroup with respect to the risky plaque features The area under the curve (AUC) of V ratio/MLD was comparable to that of CT-FFR (AUC=0.84 vs 0.88; p=0.28) and was significantly better than other parameters and for diagnosing functionally significant stenosis. For vessels with CT-FFR values below 0.70, 0.70 to 0.79, 0.80 to 0.89, and above 0.89, diagnostic accuracy of CT-FFR was 92.6%(25/27), 61.8%(34/55), 83.9%(47/56), 94.8%(55/58), respectively. For lesions with CT-FFR values ranging from 0.70 to 0.79, the accuracy could be improved to 80.0% (44/55) if these lesions were evaluated with Vratio/ MLD instead of CT-FFR.

CONCLUSION

The "grey-zone" lesions, which have CT-FFR values ranging from 0.7 to 0.8, showed lower diagnostic performance. A stepwise

approach, reserving Vratio/ MLD for "grey-zone" lesions instead of CT-FFR, can improve diagnostic accuracy.

CLINICAL RELEVANCE/APPLICATION

integrating ML based CT-FFR and V ratio/MLD allowed the most accurate discrimination between flow-limiting and non flow-limiting coronary lesions.

SSA03-05 Coronary Computed Tomography Angiography-Derived Fractional Flow Reserve in Anomalous Origin of the Right Coronary Artery from the Left Coronary Sinus

PURPOSE

To examine fractional flow reserve derived from computed tomographic angiography (FFRCT) in patients with anomalous origin of the right coronary artery from the left coronary sinus with interarterial courses (AORLIC), its relationship with patient demographics, anatomical features of AORLIC on coronary computed tomographic angiography (CCTA) images, and its clinical relevance.

METHOD AND MATERIALS

Ninety-four patients with AORLIC who underwent CCTA were retrospectively included. Anatomic features (including RCA ostium location relationship with the pulmonary valve [high or low interarterial courses], takeoff angle, degree of stenosis, etc.) associated with abnormal FFRCT values (<0.8) on CCTA were analyzed. Patient demographics and anatomical data were analyzed using binary logistic regression analysis. Receiver operating characteristic analyses were performed to describe the diagnostic performance in detecting AORLIC with normal or abnormal FFRCT values.

RESULTS

Compared to patients with normal FFRCT values, more patients with high interarterial courses and greater proximal RCA stenosis were found to have abnormal FFRCT values (all P < 0.05). AORLIC with high interarterial courses was found to be the main contributor to abnormal FFRCT values (odds ratios =4.61, 95% confidence interval [CI], 1.51-14.08; P=0.007). The corresponding sensitivity and specificity for predicting abnormal FFRCT were 57.4% and 76.6%, respectively (area under the curve=0.670, 95% CI: 0.560-0.781). AORLIC patients with abnormal FFRCT values showed a higher prevalence of typical angina (19.1% vs 4.3%, P=0.025) and atypical angina (23.4% vs 6.4%, P=0.026) compared to patients with normal FFRCT values.

CONCLUSION

AORLIC patients with abnormal FFRCT values have a higher prevalence of high interarterial courses, typical angina, and atypical angina than patients with normal FFRCT values.

CLINICAL RELEVANCE/APPLICATION

Patients with AORLHIC were more likely to have abnormal FFRCT, showing a higher prevalence of typical angina and atypical angina compared to patients with normal FFRCT values. Thus, this noninvasive FFRCT method may have potential to identify patients at risk for sudden cardiac death.

SSA03-06 Building-Block-Based 3D Deep Learning: Fully Automated Estimation of Fractional Flow Reserve from Coronary CT Angiography

PURPOSE

To evaluate the accuracy of a building-block-based fully automated 3D deep-learning model for estimating fractional flow reserve

(FFR) from whole coronary CT angiography (CCTA) data, with catheter FFR as the reference standard.

METHOD AND MATERIALS

This HIPAA-compliant, IRB-approved retrospective study of 1052 consecutive patients (mean age, 63 ± 17 years) included 131 patients whose CCTA studies showed 30%-90% stenosis in at least one segment and underwent catheter FFR, and 921 patients who underwent clinically indicated CCTA without catheter FFR. We designed a fully automated building-block-based 3D deep-learning model that inputs whole CCTA data and outputs FFR without requiring any manual segmentations. The model was trained with all 1052 CCTAs. The model comprised lumen extraction, residual extraction, and prediction blocks. In the first and second blocks, a conditional generative adversarial network and a 3D convolutional ladder network, respectively, were used to extract specific features from the CCTA by eliminating image inputs less related to FFR estimation. The prediction block estimated FFR via two independent neural networks with integrated virtual adversarial training and a self-consistency check to reduce overfitting. We used Monte Carlo cross-validation to evaluate the accuracy of the deep-learning model for estimating FFR, with catheter FFR as the reference standard.

RESULTS

Abnormal catheter FFR values (<=0.8) were observed in 55% of the labeled data (72/131). The deep-learning FFR achieved area under the curve (AUC) of the receiver-operating curve of 0.72 for detection of abnormal FFR, which is significantly higher than for CTA > 50% stenosis (AUC = 0.56). The deep-learning FFR model achieved 76% accuracy for detecting abnormal FFR, with sensitivity of 86.2% (95%CI: 80.5%-90.7%) and specificity of 61.2% (52.4%-69.5%).

CONCLUSION

The building-block-based 3D deep-learning model, performing fully automatic estimation of FFR from whole cardiac CT data, achieved accuracy of 76% for the detection of abnormal FFR.

CLINICAL RELEVANCE/APPLICATION

Our deep-learning model estimates FFR without time-consuming vessel segmentation and may greatly improve the clinical workflow when selecting patients suitable for revascularization procedures.

SSA03-07 Prediction of Lesion-Specific Ischemia from Machine Learning-Derived Fractional Flow Reserve

donghyun.yang@gmail.com

PURPOSE

This study evaluate the diagnostic performances of machine learning-based model for predicting fractional flow reserve (ML-FFR) and computed tomography (CT) derived-FFR (CT-FFR) in patients with coronary artery diseases with reference standard of invasive FFR.

METHOD AND MATERIALS

In 472 patients with coronary artery diseases, CT angiography (CTA) and invasive coronary angiography were performed with FFR in 555 lesions. CTA data were visually analyzed to evaluate the location, stenosis degrees and plaque types, and analyzed by semi-automated software to quantify computational fluid dynamics (CFD)-based CT-derived FFR. The trained ML-FFR at each point along the centerline of the coronary tree, was obtained by automated feature selection and model building from quantitative CTA. Correlation between CT-FFR and ML-FFR was obtained. The diagnostic performance of CFD-based CT-FFR and ML-FFR were compared using invasive FFR as reference standard.

RESULTS

A total of 270 lesions showed ischemia by invasive FFR (FFR <= 0.80). The correlation between CFD-based CT-FFR and ML-FFR was high (r= 0.60 - 0.99, P<0.001). CT-FFR showed moderate to high sensitivity and specificity for all lesions including left main, left anterior descending, left circumflex and right coronary arteries (Sensitivity: 55.4 - 83.3; specificity 65.1 - 73.9). For intermediate (visual stenosis grading 30-80%) lesions and tandem lesions, moderate sensitivity and specificity were observed (sensitivity: 65.1 and 62.5; specificity: 70.7 and 58.0, respectively). ML-FFR showed comparable results to CT-FFR for all lesions (Sensitivity: 57.1 - 83.3; specificity 66.5 - 77.3), and also in intermediate or tandem lesions (sensitivity: 65.1 and 62.5; specificity: 71.3 and 59.1, respectively). Compared with the CFD-based CT-FFR, the time to perform ML-FFR was shortened to a few seconds.

CONCLUSION

ML-FFR showed comparable results to CFD-based CT-FFR for the prediction of lesion-specific ischemia confirmed by invasive FFR.

CLINICAL RELEVANCE/APPLICATION

ML-FFR can be used as additional information after obtaining CTA for evaluation of coronary artery stenosis with equivalent diagnostic performance of CFD-based CT-FFR.

PURPOSE

Previous reports indicated that there was a subgroup of HCM with restrictive phenotype, which was defined by restrictive filling and reduced diastolic volumes. However, the CMR characteristics and prognosis of the restrictive phenotype has not been systematically investigated. The aim of this project was to investigate the prevalence, clinical significance, CMR characteristics and outcomes of hypertrophic cardiomyopathy (HCM) with restrictive phenotype .

METHOD AND MATERIALS

A total of 2892 consecutive patients with HCM were evaluated to identify individuals who fulfilled diagnostic criteria for restrictive phenotype. 32 patients of HCM with restrictive phenotype and 32 age and gender matched patients with typical non obstructive HCM were retrospectively enrolled.

RESULTS

The left and right atrium diameter were 55.4±4.8 mm and 61.4±8.7 mm, which were significantly larger than those of the controls ($p<0.001$); The left ventricular end-diastolic volume index, the cardiac index, and the left heart ejection fraction of patients with restrictive phenotype were all significantly less than those of the controls. The segments with late gadolinium enhancement(LGE) were 7.8±2.4 in restrictive phenotype group, which were significantly greater than controls (4.6±2.3, $p=0.004$). The 62-month survival rate was 54.1% in HCM with restrictive phenotype, compared with 91.7% in control group.

CONCLUSION

Restrictive phenotype is a special subtype of HCM. The MR features of this phenotype include mild-to-moderate left ventricular hypertrophy, severely enlarged atria, normal or small ventricles, pericardial effusion and a wide range of LGE. These patients have severe clinical symptoms and poor prognosis. MRI shows high diagnostic value in the identification of this phenotype.

CLINICAL RELEVANCE/APPLICATION

MRI shows high diagnostic value in the identification of hypertrophic cardiomyopathy with restrictive phenotype and will help indicate patients' prognosis.

SSA04-04 The Prognostic Significance of Subclinical Myocardial Deformation for Heart Failure in End-Stage

Renal Disease

loselien@live.cn

PURPOSE

This study aimed to investigate the subclinical myocardial deformation of left ventricle (LV) in end stage renal disease (ESRD) patients by cardiac magnetic resonance (CMR) tissue tracking and explore its prediction of HF.

METHOD AND MATERIALS

Sixty-two consecutive ESRD patients with preserved LV ejection fraction (LVEF>50%) and 21 age- and sex- matched healthy volunteers were prospectively recruited and underwent 3.0T CMR examination. A series of SSFP cine sequence, including short axis, horizontal 4-chamber and vertical 2-chamber long axis were scanned. LV function variables were measured. LV myocardial strain parameters such as global peak strain (PS), peak strain rate, peak velocity indices were automatically computed. After examination, patients were followed up for a duration of 11-30 months to assess HF outcome by phone contact.

RESULTS

ESRD patients with preserved LVEF had decreased radial, circumferential and longitudinal PS compared with normal controls (42.11±12.53% vs. 48.01±11.22%, -17.89±2.73% vs. -19.67±2.23%, -15.25±2.49% vs. -17.18±2.52%; respectively, all P<0.05). After a 11-30-month follow-up, 30 of 62 patients had HF. By analyzing myocardial strain data, it showed that ESRD patients suffered from HF was already found to have lower values of PS in three directions than both normal controls and patients free from HF (all P<0.05). The global circumferential and longitudinal PS were proven to be significant risk factors of HF (OR 1.294, 1.228; 95% confidence interval 1.100-1.522, 1.035-1.457; respectively, all P<0.05). A significantly lower survival rate and higher risk of HF were displayed in patients with circumferential and longitudinal PS lower than the median value. Cut-off values of PS -18.78% for circumferential and -14.54% for longitudinal to discriminate HF outcome was identified with relatively high sensitivity and specificity (AUC of 0.840, 0.821, respectively).

CONCLUSION

CMR tissue tracking provided subclinical and prognostic information to predict HF in ESRD patients before notably decreased LVEF. LV global circumferential and longitudinal PS were demonstrated to be independent risk factors of HF in ESRD patients.

CLINICAL RELEVANCE/APPLICATION

Our study proved the ability of CMR tissue tracking parameters to provide subclinical and prognostic information to predict heart failure in ESRD patients before notably decreased LVEF which may give a guidance of appropriate and early cardiovascular treatment.

SSA04-05 Value of Fractal Analysis in Identification and Further Discrimination of Isolated Left Ventricular Non-Compaction and Dilated Cardiomyopathy by Cardiac Magnetic Resonance

Sunday, Nov. 25 11:25AM - 11:35AM Room: S404CD

zhengt1116@163.com

PURPOSE

The aim of this study was to compare cardiac magnetic resonance imaging (MRI) features between isolated left ventricular non-compaction (IVNC) and dilated cardiomyopathy(DCM).

METHOD AND MATERIALS

A consecutive series of 35 patients with IVNC (males,n=23) and 30 patients with DCM (males,n=21) from a tertiary university hospital were reviewed. 20 healthy volunteers (males,n=13) were selected as control group.All groups were matched for age, gender, and body surface area. The degree of LV trabeculation was evaluated by a semi-automatic tool based on fractal analysis (FA).The resulting FD is a unitless measure value of how completely the object fills space. Myocardial deformation and Left ventricular (LV) function was assessed by feature tracking.

RESULTS

IVNC group had higher max apical FD and mean global FD than DCM group (max apical FD:1.433±0.074 vs. 1.341±0.062,P < 0.001; mean global FD:1.323±0.036 vs.1.267± 0.041, p<0.001, respectively). FDs show positively correlation with the ratio of NC/C . Compared with controls, both patient groups showed significantly reduced strain and strain rate values of all LV segments. Of note,The global longitudinal strain value of the left ventricle (GPSL) was different in the IVNC group -6.49(-11.41, -4.90) and the

DCM group -4.61(-5.87, -3.61) (P < 0.01). and Left ventricular (LV) function . The diagnostic accuracy is equivalent in univariable, but the accuracy is higher when using FDs in coordination with myocardial deformation(AUC=0.93,CI 95% [0.86; 0.98], P<0.001).

CONCLUSION

Fractal analysis can measure quantitatively the extent of non-compacted myocardium of the left ventricle, and have a definite value in the identification of pathological non-compacted myocardium and normal trabeculation. Fractal dimension combined with myocardial strain is a superior predictor of distinguishing IVNC from DCM.

CLINICAL RELEVANCE/APPLICATION

(dealing with isolated ventricular non-compaction) 'Fractal analysis based on Cine MR studies has a definite value in the identification of pathological non-compacted myocardium and normal trabeculation .'

SSA04-06 Native T1 Mapping Distinguishes Patients with Arrhythmogenic Right Ventricular Cardiomyopathy from Control Subjects

Sunday, Nov. 25 11:35AM - 11:45AM Room: S404CD

PURPOSE

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an inherited heart disease characterized by fibrofatty replacement of the myocardium. Native T1 mapping is a promising technique to quantify changes in cardiac microstructure on cardiac magnetic resonance imaging (CMR). We aimed to analyze the diagnostic value of native T1 mapping in ARVC.

METHOD AND MATERIALS

We analyzed short-axis cine 1.5 Tesla CMR images obtained using a MOLLI sequence in 51 subjects (15 ARVC patients fulfilling the 2010 diagnostic Task Force Criteria, 23 phenotype negative ARVC relatives, and 13 control subjects with right ventricular outflow tract ventricular tachycardia [RVOT VT]). Global and regional fibrosis of the left ventricle (LV) were measured as native T1 times using cvi42 (version 5.6.6, Calgary, Canada). LV segmentation was according to the 16-segment American Heart Association recommendation. We also assessed dispersion of regional T1 times, defined as the standard deviation of regional T1 times within the same patient over all analyzed segments. Diagnostic performance was assessed using ROC curve analysis.

RESULTS

Mean age was 39±17 years and 49%(25/51) were male. Mean global native T1 times were not significantly different among ARVC patients (1061±40ms p=0.085) and relatives (1053±23ms p=0.181) compared to controls (1038±27ms). However, in comparison to controls (67±12), the dispersion of regional T1 times was significantly higher in ARVC patients (91±32ms p=0.014) and relatives (77±15ms p=0.044). This was reflected in longer regional T1 times in the basal (p=0.037) and mid (p=0.013) segments in ARVC patients; and only in the basal (p=0.042) segment in relatives. More specifically, ARVC patients had longer posterolateral, inferior and anterior T1 times (p<=0.027) while relatives had longer posterolateral and inferior T1 times (p<=0.009) compared to controls. ROC analyses revealed the highest AUC for the diagnosis of ARVC using posterolateral native T1 time in both ARVC patients (AUC=0.794) and relatives (AUC=0.790).

CONCLUSION

Native T1 mapping distinguishes ARVC patients and at-risk relatives from RVOT VT controls using regional (posterolateral and inferior) T1 times.

CLINICAL RELEVANCE/APPLICATION

Early detection of ARVC is pertinent as life-threatening ventricular arrhythmias can occur. Native T1 mapping has a possible role in differentiating ARVC patient and at-risk relatives from controls.

doublep@126.com

PURPOSE

To explore the relationship between myocardial extracellular volume(ECV) and myocardial fibrosis index--collagen volume fraction(CVF) using an iron overloaded pig model by 3T MRI.

METHOD AND MATERIALS

27 pigs underwent iron dextran loading from 1 to 15 weeks. 4 controls were studied as well. T1 values were measured using a ShMOLLI sequence at 3T. Gd-DTPA was used to enhance. Measured the T1 values of the ventricular septum and left ventricular blood pool at the short axial slices of the papillary muscle respectively at plain scan and enhanced scan at the time of 20 minutes after injecting Gd-DTPA contrast medium, then calculated the ECV. Ex vivo cardiac pathology was obtained for all pigs studied. Pathological fibrosis index-collagen volume fraction(CVF) was acquired. Postmortem assessments of cardiac iron concentration(CIC) was conducted in an atomic absorption spectrophotometer. MRI measures were fitted against CVF using linear regression for the first 22 pigs. The remaining 5 were used to test the accuracy of the derived model.

RESULTS

In the experimental pigs, as dextran iron injection increased over time, the cardiac iron content increased, and myocardial collagen fibrils increased accordingly. ECV was linearly correlated to CVF (r= 0.990) in this study at 3T. By regression, the linear equations were determined as Y=-0.010+0.467X (F=1139.33,P<0.001) (Y:CVF, X:ECV). In the 5 test pigs, the predicted CVFs using the derived equations agreed well with the results quantified by pathology.

CONCLUSION

ECV are highly correlated with CVF in a novel iron overloaded pigs model. MRI quantification of myocardial fibrosis caused by iron deposited is feasible at 3T.

CLINICAL RELEVANCE/APPLICATION

Used MRI method to assess the degree of myocardial fibrosis caused by iron deposited in iron overloaded patients and developed a reliable and noninvasive techniques to measure myocardial fibrosis.

SSA04-08 Texture Analysis of Magnetic Resonance T1 Mapping with Dilated Cardiomyopathy: A Machine Learning Approach

xiaoningshao@163.com

PURPOSE

Diagnosis of dilated cardiomyopathy is a challenge in clinical radiology. We want to find out whether texture analysis parameters on magnetic resonance T1 mapping can be helpful for the diagnosis of dilated cardiomyopathy (DCM).

METHOD AND MATERIALS

We screened 50 dilated cardiomyopathy cases retrospectively and recruited 24 healthy controls prospectively between March 2015 and July 2017. T1 maps were acquired using Modified Look-Locker Inversion Recovery (MOLLI) sequence at 3.0 T MR scanner. Endocardium and epicardium were drawn on short-axis slices of T1 maps by an experienced radiologist. Twelve histogram parameters and five gray-level co-occurrence matrix (GLCM) features were extracted during texture analysis. Differences in texture features between DCM patients and healthy controls were evaluated by T-tests. Support vector machine (SVM) was used to calculate the diagnosis accuracy of those texture parameters.Schematic diagram of this study is shown on figure one.

RESULTS

Most histogram features were higher in DCM group as compared to healthy control, and nine of them had significant differences between DCM group and healthy control. As for GLCM features, energy, correlation, and homogeneity were higher in DCM group than that of the healthy control. Also, Entropy and contrast were lower in DCM group. Entropy, contrast, and homogeneity had significant differences between two groups. The diagnosis accuracy using SVM classifier with all those histogram features and GLCM features was 0.85±0.07.

CONCLUSION

A computer-based texture analysis and machine learning approach of T1 mapping could provide an objective tool for the diagnosis of dilated cardiomyopathy.

CLINICAL RELEVANCE/APPLICATION

Texture analysis of T1 mapping could provide an objective tool for the diagnosis of dilated cardiomyopathy.

SSA04-09 Fully Automated Diagnosis of Cardiomyopathy from Cardiac MR Imaging Using Convolutional Neural Networks

PURPOSE

Primary cardiomyopathies are diseases of the myocardium that are characterized by remodeling of the left ventricle and impaired cardiac function. Dilated cardiomyopathy (DCM) is a leading cause of heart failure while hypertrophic cardiomyopathy (HCM) is a common cause of sudden death. Diagnosis is made on imaging criteria but relies on manual volumetric analysis of the data and requires expertise to differentiate from other conditions which mimic cardiomyopathy. Deep learning approaches have shown promise in image classification tasks, and here we designed and evaluated a convolutional neural network (CNN) for fully-automated diagnosis of cardiomyopathy in a large sample of cardiac magnetic resonance (CMR) datasets.

METHOD AND MATERIALS

The study cohort consisted of 1,069 adult participants: 311 patients with DCM, 396 patients with HCM and 362 healthy volunteers (HV) matched by gender, age and body surface area. All subjects had a conventional CMR including retrospectively-gated cine imaging. The 4-chamber cine sequence was used for analysis and passed to a 6-layer convolutional neural network implemented in TensorFlow. Five convolutional layers, with between 64 and 128 nodes, were followed by a fully-connected 128-node layer. A predicted classification was obtained from an output later with a SoftMax activation function. The model was trained over 100 epochs using a Titan X GPU. Four-fold cross validation was performed with results reported as mean accuracy.

RESULTS

All subjects were included in the analysis. Processing time per subject was approximately 2 seconds. In total 80/82 DCM, 84/97 HCM and 87/87 HV participants were correctly classified in the held-out data. Overall, 251/266 participants were correctly classified (94.3%).

CONCLUSION

Cardiomyopathy can be diagnosed with a high degree of accuracy through direct analysis of time-resolved CMR imaging using a CNN. This includes correctly excluding disease in every healthy adult. Future work will include simultaneous analysis of cine sequences in different cardiac planes and external validation of the model on an independent cohort.

CLINICAL RELEVANCE/APPLICATION

These findings demonstrate the potential of an automated method to efficiently and objectively diagnose cardiomyopathy on cardiac MRI.

PURPOSE

To evaluate the impact of 1024 matrix size and photon-counting-detectors (PCDs) relative to 512 matrix size and energy-integrating-detectors (EIDs) for chest CT.

METHOD AND MATERIALS

22 adult patients undergoing clinically indicated chest CT received dose-matched PCD CT after written informed consent. 1.5 mm images were reconstructed at a 1mm overlap with our routine clinical kernel (B46) at both 512 and 1024 matrix sizes for EID scans. For PCD, B46 and an additional sharp kernel (Q65, not available for EID) was reconstructed at a 1024 matrix. Two chest radiologists compared only the right lung of B46/EID/1024; B46/PCD/1024 and Q65/PCD/1024 images in a side-by-side fashion to the routine clinical B46/EID/512 images, noting the highest level bronchus clearly identified in each lobe. The 3rd and 4th order bronchi were specifically evaluated and any lung nodules were compared to the B46/EID/512 images using a 5 point Likert scale (+2 = improved detection confidence, +1=preferred but no confidence change, 0 = similar, -1=worse but no confidence change, -2=worse with decreased confidence). Statistical analysis was performed using a Wilcoxon signed rank test with a $p < 0.05$ considered significant.

RESULTS

Compared to B46/EID/512, readers detected higher order bronchi using Q65/PCD/1024 images for every lung lobe ($p<0.002$). For B46/EID/1024 reconstruction, higher order bronchi were only significantly better seen in the right middle lobe ($p=0.007$). Readers were able to better identify bronchial walls of the 3rd and 4th order bronchi better using Q65/PCD/1024 (mean Likert-scores of 1.1 and 1.5), which was significantly higher compared to B46/EID/1024 or B46/PCD/1024 (mean difference 0.8; $p<0.0001$). Of 49 non-calcified pulmonary nodules (8 part solid, 41 solid), Q65/PCD/1024 had a slightly but significantly higher mean visualization score of 0.8 compared to 0 for B46/EID/1024 and 0.2 for B46/PCD/1024 ($p<0.0002$).

CONCLUSION

Lung PCD-CT with 1024 matrix using a sharp Q65 kernel increase visualization of higher order bronchi and bronchial walls without compromising nodule detection. Softer kernels and further work are needed to examine the internal density characteristics of nodules at PCD-CT.

CLINICAL RELEVANCE/APPLICATION

PCD-CT with 1024 matrix improves visualization of medium and small bronchi compared to current routine chest CT, creating an opportunity for radiologists to better characterize lung pathology.

SSA05-02 Normalized Emphysema Score Progression: An Improved CT Biomarker for Mortality

PURPOSE

Normalized emphysema score (normES) is a protocol-robust and validated CT biomarker for mortality. We aimed to improve mortality prediction by modelling its change over time.

METHOD AND MATERIALS

CT scans from all 1810 deceased participants from the National Lung Screening Trial were selected. Of these, 445 died from lung cancer. A random selection of 4190 surviving participants were sampled with replacement up to 24432 to approximate the full cohort. The normES was obtained by computing the emphysema scores after resampling, normalization, and bullae cluster analysis. The reference models contained solely the baseline (T0) normES. To investigate if progression of emphysema provides additional information, normES from the first (T1) and second annual screening rounds (T2) and normES progression (normESprog) were added to the base model. normESprog was calculated by subtracting the T0 log(normES) from the T1 or T2 log(normES) and dividing by the time in between. Proportional hazard models predicting all-cause and lung cancer mortality were compared by calculating the continuous net reclassification improvement (NRI) for each year of follow-up.

RESULTS

The analysis of T0 and T1 data was performed on 22695 samples; 3547 lacked T0 or T1 scans, or had corrupted data. NRI improvement for all-cause and lung cancer mortality prediction compared to the base models were 4.5% (95%CI: -7.3 to 8.4%) and 4.1% (-9.3 to 14.6%) 3 years after baseline, 6.1% (-5.3 to 9.4%) and 0.1% (-7.1 to 12.2%) after 5 years, and 6.1% (-6.2 to 8.7%) and -0.4% (-5.6 to 11.3%) after 7 years, respectively. When modelling the T0 to T2 interval, another 2603 samples were excluded. For all-cause mortality, the 3, 5, and 7 year time points showed respective NRI improvements of -0.5% (-6.7 to 8.0%), 10.8% (5.5% to 14.7%), and 12.2% (7.1% to 15.6%). Improvements in lung cancer mortality prediction were -6.1% (-24.0 to 12.6%), 19.6% (10.6 to 29.2%), and 24.1% (15.4% to 31.7%), respectively. All hazard models had a logrank test p<.001.

CONCLUSION

Two normES measurements are better than one at predicting mortality over longer periods of time. The time between normES measurements should be sufficiently distant to account for the slow progression of emphysema.

CLINICAL RELEVANCE/APPLICATION

Normalized emphysema score progression is an automatic emphysema quantification method which can better predict the long-term mortality than a single baseline measurement.

SSA05-03 Comparison of Two Independent Visual Assessment Protocols for the Detection of Emphysema in the National Lung Screening Trial Cohort

Sunday, Nov. 25 11:05AM - 11:15AM Room: E451A

tsevco22@gmail.com

PURPOSE

To investigate the variability in assessing the presence of emphysema in a lung cancer screening population using low-dose CT scans and compare this to rates of spirometry-detected airflow obstruction.

METHOD AND MATERIALS

Baseline low-dose CT scans from 6,352 NLST participants enrolled in the CT arm who also underwent spirometry were evaluated. Emphysema was visually assessed in NLST as present or absent. In our study, two readers visually assessed CT scans using a modified NETT protocol that divided the lung into upper, middle, and basal zones and graded emphysema as none (0%), trace (1-25%), mild (25-50%), moderate (50-75%), or severe (75%+). In this protocol, a subject was scored as positive if any region was scored trace or greater. Results were compared to emphysema and spirometry data from the Pittsburgh Lung Screening Study (PLuSS).

RESULTS

Among the 6,352 subjects, emphysema was identified in 55.4% (3518/6352) of subjects in NLST and 40.4% (2566/6352) of subjects using our protocol (agreement Kappa=0.4990). Emphysema severity in the current study was reported as none, trace, mild, moderate, and severe in 59.6%, 27.4%, 7.0%, 4.1%, and 1.9% of the subjects, respectively. Inter-reader agreement for the presence of emphysema between the two readers in our study in 200 CT scans was moderate to substantial (K=0.6073). Using the McNemar test statistic, there was a statistically significant difference between our visual assessment of emphysema and the NLST assessment of emphysema ($p < 0.001$). Spirometry-detected airflow obstruction was reported in 32.0% of the NLST subjects. In PLuSS (n=3638), emphysema and airflow obstruction were identified in 42.5% and 42.7% of the subjects, respectively.

CONCLUSION

Our study revealed a significant disagreement in emphysema assessment between two independent visual interpretations of low-dose CT scans. The discrepancy between emphysema and airflow obstruction (55.4% versus 32.0%) in the NLST-ACRIN subcohort appears to be from overdetection of emphysema. Our visual emphysema assessment of NLST CT scans is more consistent with rates of spirometry-detected airflow obstruction and with previously published rates of emphysema in lung cancer screening populations.

CLINICAL RELEVANCE/APPLICATION

Since emphysema is recognized as a significant risk factor for lung cancer, our study demonstrates the need to standardize and improve emphysema assessment in low-dose lung cancer screening CT scans.

SSA05-04 Visual Presence of Emphysema Predicts Progression of Emphysema and Air Trapping in Cigarette Smokers

PURPOSE

Visual categorization of emphysema on CT has been shown to correlate with symptomatic impairment and with mortality. However, the relationship between presence of emphysema and subsequent progression of disease has not previously been evaluated.

METHOD AND MATERIALS

We studied 4126 subjects enrolled in the COPDGene study, who had visual CT scores at baseline, and quantitative inspiratory and expiratory CT at baseline and at 5 years. Trained research analysts performed visual classification of parenchymal emphysema on baseline volumetric CT scans of these subjects using the Fleischner Society classification system. Each scan was independently evaluated by two analysts; discordances between analysts were adjudicated by a thoracic radiologist. Statistical analysis used a linear mixed model, adjusted for age, height, gender, race, smoking status, scanner make, and reconstruction algorithm, with dependent variables being inspiratory lung density at 15th percentile (adjusted for lung volume) as a measure of emphysema, and % of lung voxels < -856 HU on expiratory CT (LAA-856) as a measure of air trapping. Analysis was stratified by presence or absence of COPD at baseline.

RESULTS

In subjects with COPD, those with parenchymal emphysema at baseline showed a lung density decline of 4.7 g/l (95% CI 3.9, 5.4, $p<0.0001$), compared with 1.4 g/l (0.5, 2.4, $p=0.003$) for those without emphysema. For subjects without COPD, corresponding values were 4.0 (3.2, 4.9, $p<0.0001$) and 0.8 (0.25, 1.4. $p=0.005$). In subjects with COPD, those with baseline emphysema showed increase of 3.8% (2.9, 4.6, $p<0.0001$) in LAA-856, compared with 0.5% (-0.6, 1.5, n.s.) for those without. For subjects without COPD, those with emphysema had an increase in LAA-856 of 1.7% (1.1, 2.4, $p<0.0001$), while those without emphysema had a slight decrease of 0.5% (0.1, 0.9, $p=0.01$).

CONCLUSION

The presence of parenchymal emphysema at baseline is associated with a higher rate of progression in emphysema and air trapping at 5 year follow-up, in cigarette smoking subjects with and without COPD.

CLINICAL RELEVANCE/APPLICATION

The presence of visible emphysema on CT in cigarette smokers is an important predictor of subsequent progression.

SSA05-05 3D Oxygen-Enhanced MRI at 3T System versus Thin-Section CT: Quantitative Capability for Pulmonary Functional Loss Assessment and Clinical Stage Classification in Smokers

PURPOSE

To prospectively and directly compare the quantitative capability for pulmonary functional loss assessment and clinical stage classification between 3D oxygen-enhanced MR imaging (O2-enhanced MRI) and thin-section CT in smokers.

METHOD AND MATERIALS

Twenty consecutive smokers (12 men and 8 women; age rang 56-85 years) underwent 3D O2-enhanced MRI, thin-section CT and pulmonary function test (FEV1/FVC%, %FEV1% and %DLCO/VA). All smokers were classified into four stages ('Without COPD', 'Mild COPD', 'Moderate COPD', 'Severe or very severe COPD') according to the GOLD guideline. For 3D O2-enhanced MRI in each smoker, 3D Fast Field Echo sequence with variable flip angles was performed with and without 100% oxygen inhalation at a 3T MR system. With non-rigid registration software, regional T1 value change map was generated from O2-enhanced MR data by pixel by pixel analyses. Then, ROIs were placed over the lung on all slices, and averaged to determine mean T1 value change (ΔT1) in each subject. On quantitative CT in each subject, percentage of low attenuation area within entire lung (LAA%) was also measured. To compare the capability for pulmonary functional loss assessment, both indexes were correlated with each parameter. Then, both indexes were compared four clinical stages by Tukey's HSD test. Finally, discrimination analyses were performed, and accuracy was compared each other by McNemar's test.

RESULTS

ΔT1 and LAA% were significantly correlated with FEV1/FVC% (ΔT1: r=-0.70, p=0.0006; LAA%: r=-0.75, p=0.0002), %FEV1 (ΔT1: r=-0.84, p<0.0001; LAA%: r=-0.67, p=0.0013) and %DLCO/VA (ΔT1: r=-0.69, p=0.0009; LAA%: r=-0.63, p=0.0029). ΔT1 had significant difference between 'Severe or very severe COPD' group and others (p<0.05), although LAA% had significant difference between 'Severe or very severe COPD' and 'Without COPD' (p<0.05) or 'Mild COPD' (p<0.05) groups. Discrimination accuracies of ΔT1 (73.7 [14/19] %) was significantly higher than that of LAA% (42.1 [8/19] %, p=0.03).

CONCLUSION

3D O2-enhanced MRI has a better capability for pulmonary functional loss assessment and clinical stage classification in smokers than quantitative CT.

CLINICAL RELEVANCE/APPLICATION

3D O2-enhanced MRI has a better capability for pulmonary functional loss assessment and clinical stage classification in smokers than quantitative CT.

SSA05-07 Using Deep Learning to Predict Emphysema in Early Lung Cancer Screening Low-Dose CT Scan

PURPOSE

The patients who are recommended for annual lung cancer screening are at a higher risk for other cardiopulmonary diseases. Therefore, it would be beneficial to use the low-dose CT scans (LDCT) to identify other conditions. This work aims to demonstrate the feasibility of using deep learning method to identify findings, specifically emphysema.

METHOD AND MATERIALS

The dataset consists of 860 cases of LDCT scans from a lung screening program. Emphysema was identified on each scan as none, mild, moderate, or severe. To evaluate the effect of potential labeling error caused by per case rating system, three different approaches were taken: 1) using the entire lung region, 2) using only the top 50% of the lung since emphysema due to smoking tends to affect the upper lobes more than the lower lobes, and 3) using only the bottom 50% of the lung as a control. Deep learning consisted of feature extraction using a pre-trained VGG-19 network followed by a support vector machine binary classifier that predicted the presence of emphysema (none vs. moderate and severe). The predictions were first performed on a per slice basis and averaged to acquire per case prediction. The area under the receiver operating characteristic curve (AUC) was used to evaluate the performance.

RESULTS

Per slice prediction for the entire lung region, the top 50%, and the bottom 50% produced an AUC of 0.76 (SE: 0.01), 0.77 (0.01), and 0.74 (0.01), respectively. Per case prediction produced an AUC of 0.84 (0.03), 0.83 (0.03), and 0.80 (0.03). The higher AUCs for per case prediction demonstrates that aggregating the predictions on slices help reduce the effect of labeling errors. The AUCs for the bottom 50% are lower, but still on par, which is likely due to the fact emphysema does not completely spare the bottom lobes.

CONCLUSION

We have demonstrated the potential of transfer learning to predict the presence of emphysema on LDCT scans. Fine-tuning work is currently on-going, and given the high performance already achieved with transfer learning, fine-tuning is likely to achieve even higher performance.

CLINICAL RELEVANCE/APPLICATION

LDCT provides an opportunity to identify other pathologies that may otherwise go undiagnosed. Having a suite of algorithms that automatically searches for multiple incidental findings has the potential to increase efficiency and prevent missing important findings.

SSA05-08 Inspiratory/Expiratory Xenon-Enhanced Area-Detector CT with and without 3D Motion Analysis: Capability for Pulmonary Functional Loss Assessment and Clinical Stage Classification of COPD

Sunday, Nov. 25 11:55AM - 12:05PM Room: E451A

PURPOSE

To prospectively evaluate the utility of 3D lung motion assessment on inspiratory/expiratory xenon-enhanced area-detector CT (Xe-enhanced ADCT) for pulmonary functional loss assessment and clinical stage evaluation of chronic obstructive pulmonary disease (COPD).

METHOD AND MATERIALS

Twenty-eight consecutive patients with and without COPD (18 men and 10 women; mean age, 72 years old) prospectively underwent inspiratory/expiratory Xe-enhanced ADCT examinations as well as pulmonary function tests. Then, all patients were classified by GOLD classification as follows: 'Without COPD', 'Mild COPD', 'Moderate COPD' and 'Severe or Very Severe COPD'. In each subject, Xe-enhanced ADCT data was transferred to our proprietary software to generate xenon ventilation maps such as wash-in (WI), wash-out (WO) and ventilation ratio (VR: VR=[WI-WO]/WI) maps as well as 3D motion magnitude maps at X-, Y- and Z-axes as well as expansion rate (ER) map by Jacobian method by pixel-by-pixel analyses. Then, each regional index was assessed by ROI measurements, and each final value was determined as averaged value. To determine the relationship between xenon ventilation- and 3D motion-based indexes, Pearson's correlations were performed. Then, step-wise regression analyses were performed between all indexes and %FEV1. Finally, discrimination accuracies were performed among xenon-ventilation indexes, 3D-moion based indexes and combined method by McNema's test.

RESULTS

WO had significant and correlations with X, Y and Z-axis motion magnitudes (-0.53 **CONCLUSION**

3D lung motion assessment is useful for pulmonary functional loss and clinical stage classification of COPD, when applied with inspiratory/expiratory Xe-enhanced ADCT.

CLINICAL RELEVANCE/APPLICATION

Inspiratory/expiratory xenon-enhanced area-detector CT with 3D lung motion assessment is more useful than that without 3D lung motion assessment for pulmonary functional loss and clinical stage classification of COPD.

SSA05-09 A Convolutional Neural Network Approach to Imaging-Based Pulmonary Measurements in COPD Patients

PURPOSE

Chronic obstructive pulmonary disease (COPD) affects over 16 million Americans and 251 million people worldwide. Multiple patterns of pathology exist, and imaging measurements are increasingly important for identifying COPD subtypes and prognosis. We hypothesized that a convolutional neural network (CNN) could predict volumetric measurements relating to pulmonary function, based on a subset of chest CT images.

METHOD AND MATERIALS

With HIPAA compliance and IRB approval, we retrospectively identified inspiratory CT scans for 160 COPD patients from our institution enrolled in the COPDGene multicenter study. We used a CNN based on VGG19 to develop regression-based inference predictions of total lung capacity (TLC), functional residual capacity (FRC), and percentage of emphysema. Measurement of these parameters was obtained previously as part of the larger COPDGene dataset, and has been discussed by other groups. A subset of 10 equally spaced axial chest images were selected from the full chest CT and used to train the network, with assessment by five fold cross validation. Correlations between CNN and ground truth are given as R2, and bias was assessed with Bland-Altman plot analysis.

RESULTS

CNN predicted measurements of TLC were correlated with those from the COPDGene dataset with an R2 value of 0.86 (slope 1.10), and mean difference of 0.14L ± 0.57L. FRC was correlated with an R2 value of 0.84 (slope 1.26), and mean difference of -0.06L ± 0.56L. Percent emphysema was correlated at an R2 value of 0.82 (slope 1.04), and mean difference of 0.15% ± 3.34%.

CONCLUSION

Here we show the ability of a CNN to produce well correlated predictions of pulmonary volume measurements, inferred from a subset of chest CT images. Refinement of this CNN can expand it to additional structures or volumes, and may allow automation of quantitative pulmonary function measurements and volumes to streamline disease monitoring.

CLINICAL RELEVANCE/APPLICATION

We present a convolutional neural network capable of making well-correlated, inference-based, predictions of pulmonary volume measurements in COPD patients, based on a subset of 10 chest CT slices.

SSA06-02 Acute Pancreatitis: A Quantitative Analysis of Iodine with Dual-Energy Spectral Computed Tomography

Sunday, Nov. 25 10:55AM - 11:05AM Room: S405AB

Participants
Wei Wei, Hefei, China (*Presenter*) Nothing to Disclose

For information about this presentation, contact:

weiweill@126.com

PURPOSE

To investigate the correlation between iodine concentration and clinical severity of acute pancreatitis (AP) through the quantitative evaluation with dua-energy spectral computed tomography (DESCT), so as to find out an effective imaging technology in the evaluation of clinical severity of AP.

METHOD AND MATERIALS

Sixty patients with AP confirmed clinically (AP group) and 30 patients with normal pancreas (control group) were retrospectively analyzed. All the patients underwent enhanced CT scan in the spectral imaging mode. Iodine concentration and normalized iodine concentration (NIC) were respectively measured during arterial phase and portal phase in the material-decomposition images by using a spectral imaging viewer (GSI Viewer).

RESULTS

Iodine concentration and NIC were significantly higher in the control group than in the AP group ($P<0.05$, $P<0.001$). In the AP group, according to Ranson grading, 24 patients were in the mild grade, 20 patients were moderate, and 16 patients were severe. Iodine concentration and NIC decreased along with the increase of their Ranson grade. There were significant difference in iodine concentration and NIC among the three subgroups (iodine concentration on arterial phase: $F=8.776$, $P<0.01$; iodine concentration on portal phase: $F=4.019$, $P<0.05$; NIC on arterial phase: $F=12.700$, $P<0.001$; NIC on portal phase: $F=8.732$, $P<0.01$). Iodine concentration and NIC on arterial and portal phases in the mild grade group were both significantly higher than those in the moderate grade group ($P<0.05$); however, iodine concentration on arterial and portal phases, and NIC on arterial phase in the severe grade group were significantly lower than those in the moderate grade group ($P<0.05$).

CONCLUSION

DESCT can analyze hemodynamic changes in AP quantitatively, which is of great value in evaluating changes in AP of each grade.

CLINICAL RELEVANCE/APPLICATION

The quantitative evaluation of iodine with dua-energy spectral computed tomography (DESCT) provide a new method for the prognosis of patients with acute pancreatitis.

SSA06-03 Diagnostic Performance of Dual Energy CT Characterization of Incidental Renal Lesions in Emergency

PURPOSE

To assess the diagnostic performance of DECT characterization of incidental, indeterminate renal lesions detected on routine contrast-enhanced CT in ER patients, using reference standard of renal mass protocol CT or MRI.

METHOD AND MATERIALS

The study cohort included patients with an indeterminate lesion on portal venous phase DECT (homogeneous lesion of greater than 20 HU, or complex cystic lesion), with reference standard imaging (renal mass protocol CT or MRI) of the lesion performed within 2 years. All DECT scans were performed in the ER setting on the same dual source DECT scanner. Two radiologists with DECT experience used DECT post-processed iodine selective images to characterize lesions as: definitely non-enhancing, equivocal/possible enhancement, or definitely enhancing; readers also measured iodine concentration within lesions. Two expert abdominal radiologists evaluated reference standard imaging of each lesion, categorizing each as definitely non-enhancing (Bosniak I and II cysts), equivocal/possible enhancement (Bosniak IIF or other lesions needing follow up), and definitely enhancing (solid mass, Bosniak III/IV cysts).

RESULTS

66 lesions were included in the study cohort, on reference standard imaging 44 were non-enhancing (11 Bosniak I and 33 Bosniak II cysts) and 22 were lesions with equivocal or definite enhancement (7 Bosniak IIF cysts, 3 Bosnaik III cysts, 3 Bosniak IV cysts, 9 solid masses). Qualitative assessment of lesions as enhancing on by DECT readers on iodine selective images had a sensitivity of 100%, specificity of 43%, positive predictive value of 47%, negative predictive value of 100%, and accuracy of 62%.

CONCLUSION

Characterizing incidental indeterminate renal lesions on portal venous phase DECT as non-enhancing with DECT post-processing was successfully able to exclude enhancement in these lesions (NPV of 100%), indicating that incidental lesions without enhancement on DECT are highly likely to be Bosniak I or II cysts. However, the specificity and positive predictive value of enhancement seen on DECT were relatively low. Further research is needed to assess methods to mitigate false positive enhancement with DECT.

CLINICAL RELEVANCE/APPLICATION

Qualitative assessment of enhancement of incidental renal lesions with DECT had a high negative predictive value, indicating that lesions without enhancement on DECT post-processed images are highly likely to be Bosniak I or II cysts.

PURPOSE

To assess the impact of socioeconomic status on CT findings and the management of acute appendicitis.

METHOD AND MATERIALS

Informed consent was waived for this IRB-approved, HIPAA compliant, retrospective study of 18-64 year old patients with acute appendicitis at our institution by MDCT from 1/1/2006-12/31/2016 (n=1886). Insurance, race/ethnicity, primary language, and education level were obtained from the electronic medical record. Multivariate linear regression was performed to determine crude and adjusted parameter estimates for length of stay. For each metric, the estimates generated from linear regression are interpreted as difference in length of stay associated with one unit change in each covariate. Logistic regression models were run and crude and adjusted odds ratio (OR) were calculated for each categorical outcome. A P value of less than 0.05 was considered statistically significant for all analyses. Statistical computations were performed on SAS 9.3 system (SAS Institute, Cary, NC).

RESULTS

Free care/Medicaid/Medicare subjects had 0.4 days increase in length of stay as compared to private insurance (p=0.039). Free care/Medicaid/Medicare subjects were also found to have increase odds of surgical site infection or re-operation (OR=1.93, 95% CI= 1.03-3.63, p=0.041), as compared to private insurance patients. Hispanics were associated with lower odds of complicated CT findings (OR=0.55, 95% CI=0.335-0.898, p=0.017), and both Hispanic and Blacks had lower odds of perforation, abscess, or gangrene by intraoperative report (OR=0.67, 95% CI=0.47-0.97, p=0.035; OR=0.68, 95% CI=0.48-0.97, p=0.033, respectively), as compared to Whites. There were no statistically significant differences in CT findings, length of stay, or post-operative complication by primary language or education level.

CONCLUSION

Acute appendicitis is a common emergent illness presenting across the socioeconomic spectrum. Free care, Medicaid and Medicare patients have increased length of stay and increased odds of post-operative complication. Hispanics show lower odds of complicated CT findings on initial presentation. Hispanics and Blacks have lower odds of having complicated intraoperative findings.

CLINICAL RELEVANCE/APPLICATION

Further investigation on the impact of socioeconomic status within radiology and the potential for radiologists to join the fight in combating health disparity are necessary to eliminate health inequality.

Honored Educators

Presenters or authors on this event have been recognized as RSNA Honored Educators for participating in multiple qualifying educational activities. SSA06-05 Virtual Monoenergetic Dual-Energy CT for Evaluation of Hepatic and Splenic Lacerations

Sunday, Nov. 25 11:25AM - 11:35AM Room: S405AB

Awards
Student Travel Stipend Award

Participants
Ellen X. Sun, MD , Boston, MA (*Presenter*) Nothing to Disclose
Jeremy R. Wortman, MD, Boston, MA (*Abstract Co-Author*) Nothing to Disclose
Jennifer W. Uyeda, MD, Boston, MA (*Abstract Co-Author*) Consultant, Allena Pharmaceuticals, Inc; Invited Speaker, Siemens AG
Roger Lacson, Boston, MA (*Abstract Co-Author*) Nothing to Disclose
Aaron D. Sodickson, MD,PhD, Boston, MA (*Abstract Co-Author*) Institutional research agreement, Siemens AG; Speaker, Siemens AG; Speaker, General Electric Company

PURPOSE

To evaluate the utility of virtual monoenergetic imaging in assessing splenic and hepatic lacerations and to determine the optimal energy level to maximize laceration contrast-to-noise ratio.

METHOD AND MATERIALS

We retrospectively examined 26 contrast-enhanced abdominal CT studies performed on a dual-source dual-energy CT (DECT) scanner in our Emergency Department from 2013 to 2017, with liver and/or splenic lacerations. All studies included portal venous phase imaging acquired simultaneously at low (80 or 100 kVp) and high (140 kVp with tin filtration) energy levels. Conventional 120 kVp-equivalent mixed images were generated for routine review by blending the low and high energy acquisitions. Virtual monoenergetic reconstructions were retrospectively generated in 10 keV steps from 40-90 keV. Liver or splenic laceration attenuation, background parenchymal attenuation and noise were measured on each set of monoenergetic and mixed images. Injury-to-parenchyma contrast and contrast-to-noise ratios (CNR) were calculated. Differences between CNR of monoenergetic series and mixed images were assessed with a paired t-test.

RESULTS

Liver laceration was identified in 17 patients, and splenic laceration in 10 patients. Background noise was lower at higher monoenergetic levels, with the lowest noise seen at 90 keV, equivalent to that of mixed images (8.26 for 90 keV and 8.66 for mixed, p=0.035). For liver and splenic lacerations, CNR at 40-60 keV was higher than that of mixed images. Injury-to-parenchyma CNR was highest at 40 keV, significantly higher than mixed images (mean CNR 6.14 for 40 keV, 5.48 for mixed, p=0.024). Subgroup analysis of liver and splenic lacerations demonstrated a significant improvement in CNR at 40 keV compared with mixed images for splenic lacerations (5.89 vs. 4.98, p=0.036); for liver lacerations, the increased CNR at 40 keV compared with mixed images was not statistically significant (6.29 vs. 5.77, p=0.2).

CONCLUSION

With DECT virtual monoenergetic imaging, the optimal energy level for assessing liver and splenic lacerations was 40 keV, which showed improved injury-to-parenchyma CNR compared with traditional polyenergetic reconstructions.

CLINICAL RELEVANCE/APPLICATION

Virtual monoenergetic imaging at low keV can improve contrast to noise ratio of hepatic and splenic lacerations, which may improve

detectability of subtle injuries and aid radiologists in classifying these injuries.

SSA06-06 Emergency Department Would Become the New Diagnostic Center if the Trend in National Imaging Utilization Continues

Sunday, Nov. 25 11:35AM - 11:45AM Room: S405AB

Participants
Santosh K. Selvarajan, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

For information about this presentation, contact:

santosh.rad@gmail.com

PURPOSE

Policymakers and payers have been concerned with the rapid growth in imaging utilization particularly in the Emergency Departments. Our purpose is to study the trends in utilization of imaging in EDs in recent years, by modality. Secondly, to determine the specialty of the interpreting physicians.

METHOD AND MATERIALS

The nationwide Medicare Part B Physician/Supplier Procedure Summary Master Files for 2004-2016 were the data source. CPT codes for plain radiography (XR), non-cardiac ultrasound (US), CT, MRI, and nuclear medicine (NM) were aggregated by modality. Medicare's place-of-service codes were used to identify those exams done during ED visits, and its specialty codes were used to determine which specialties did the interpretations. Trends from 2004 to 2016 were assessed.

RESULTS

Between 2004 and 2016 in the ED, the utilization of CT increased from 2,842,446 in 2004 to 7,705,340 in 2016 (+103%). MRI studies increased from 69,000 to 286,000 (+204%). The number of non-cardiac ultrasounds grew from 408,000 to 1,024,809 (+151%). The radiographs performed grew from 9,471,777in 2004 to 13,177,023 in 2016 (+31%). The Nuclear Medicine studies showed a slight numerical decline, from 106,792 in 2004 to 65,985 in 2010 (-25%), but this was largely due to code bundling that occurred in myocardial perfusion imaging in 2010. Nuclear Medicine studies slightly increased from 65,985 in 2010 to 78,000 in 2016 (+11%). In each of the first 4 modalities, growth was steady and progressive with no evidence of slowing even after code bundling for CT abdomen and pelvis. Radiologists' share of the interpretations in 2016 were: CT 99%, MRI 99%, XR 98%, US 87.5%, NM 95%

CONCLUSION

The utilization of imaging in EDs grew substantially from 2004 to 2016 in comparision to the utilization in other places where imaging is performed. The largest numerical increases were seen in CT and XR. Radiologists strongly predominate in interpreting in all modalities.

CLINICAL RELEVANCE/APPLICATION

The progressive growth of utilization is of concern and suggests that more interdepartmental cooperation is needed for appropriate use of imaging in EDs.

PURPOSE

In the emergency department (ED), imaging studies are requested by a wide spectrum of healthcare providers, many of whom are not educated in the finer details of imaging protocols. This lack of expertise leads to suboptimal diagnostic imaging; this results in decreased diagnostic accuracy, unnecessary cost and added radiation, among other potential inefficiencies. While order entry algorithms been implemented, they are not a comprehensive solution. This study demonstrates the value of radiologists' input on diagnostic imaging at the time of order entry.

METHOD AND MATERIALS

Contrast enhanced CT/CT Angiogram (CTA) exams ordered in our ED are subject to validation by radiologist/radiology physician assistant. If the ordered study is deemed to be suboptimal, the provider is contacted and better options are discussed. Subsequently, the optimal study is protocolled. Per IRB, this quality improvement study was not subject to review. Ordered CT/CTA exams of the chest, abdomen or pelvis were reviewed over the course of 90 ED shifts (10pm-7am) spanning from 9/2017-3/2018. Total CT exam orders placed and the number of exams that were ultimately modified were recorded.

RESULTS

During the study, 631 eligible exam orders were reviewed. 14% (88/631) of the requests were modified. Of these modifications, 15% (13/88) were cancellations. In 84% (63/75) of alterations, contrast was improperly used. Suggested order alterations were more often related to oral contrast (52%, 38/75) than intravenous contrast (31%, 23/75). The anatomic area scanned was changed in 15% (11/75) of modified exams. In 13% (10/75) of modified exams, the type of study was changed entirely (Fig. 1).

CONCLUSION

In the era of value-based health care, it is essential to tailor patients' imaging to address specific clinical questions. Our results demonstrate that approximately 14% of diagnostic CT orders requested in the ED are not optimized. Most commonly, mistakes are related to contrast. Having radiology staff available to identify suboptimal diagnostic CT orders can add value to patient care by optimizing contrast protocols, ensuring the clinical question will be addressed and avoiding redundant examinations.

CLINICAL RELEVANCE/APPLICATION

In the ED, active monitoring of CT scan requests by a radiologist/trained radiology staff can further optimize diagnostic imaging, despite the availability of clinical decision support.

SSA06-08 National Trends of Non-Cardiac Ultrasound in the Emergency Department: What's the Contribution of Non-Radiologists?

Sunday, Nov. 25 11:55AM - 12:05PM Room: S405AB

Participants
Santosh K. Selvarajan, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

For information about this presentation, contact:

santosh.rad@gmail.com

PURPOSE

The Accreditation council for Graduate Medical Education (ACGME) requires Point of Care Ultrasound (POCUS) training to be part of Emergency Medicine. Our purpose was to determine recent trends in Non-cardiac ultrasound utilization in Emergency Departments. Secondly, assess the contribution of Non-Radiologists interpretations from 2004 to 2016.

METHOD AND MATERIALS

The Medicare Physician/Supplier Procedure Summary Master Files for 2004-2016 were used. The codes for ED Ultrasound were selected for 2004 and 2016. The procedure volumes in ED settings were calculated. Then Medicare provider specialty codes were used to identify those exams interpreted by Radiologists and other specialties.

RESULTS

The number of non-cardiac ultrasounds grew from 408,000 in 2004 to 1,024,809 in 2016 (+151%). Radiologists interpreted 87.5% of all ED non-cardiac ultrasounds. The vascular surgeons and emergency physicians interpreted 4% each, cardiologists and other surgical subspecialties interpreted the remaining 4.5%. There is 181% increase in the studies interpreted by vascular surgeons (15820 in 2004 to 44,369 in 2016), 1117% increase in the studies interpreted by emergency physicians (3459 in 2004 to 41400 in 2016), 26% increase by surgical specialties (14502 in 2004 to 18351 in 2016), and 140% increase by cardiologists (5270 in 2004 to 12470 in 2016).

CONCLUSION

The utilization of non-cardiac ultrasound grew substantially from 2004 to 2016. Radiologists continue to predominate in interpreting ED ultrasounds. There is small but substantial growth of emergency physicians and vascular surgeons' interpretations. Although much small in number the interpretations by cardiologists and other surgical specialties have also slowly increased.

CLINICAL RELEVANCE/APPLICATION

Although Non-Radiologists interpreting non-cardiac Emergency ultrasound has slowly grown, future studies are needed to assess the complexity of studies interpreted by them.

SSA06-09 Tiered Response Algorithm for Endovascular Management of Traumatic Hemorrhage

Sunday, Nov. 25 12:05PM - 12:15PM Room: S405AB

bsadeghi@uci.edu

PURPOSE

Hemorrhagic shock represents the second-leading cause of early death in traumatic injury with endovascular therapy as an integral part of the therapeutic armamentarium. The emphasis on a rapid response is balanced with the judicious utilization of resources that led to the creation of a tiered algorithm. The purpose of this study is to assess the efficacy of such a response for the

management of non-operative traumatic hemorrhage.

METHOD AND MATERIALS

A retrospective review of after-hour trauma activations was performed at a level 1 trauma center from July 2015 to July 2017. Activation of the interventional team was initiated either immediately ("EmboNow"), prior to imaging review and attending interventional radiologist (IR) approval, or after review and discussion with IR ("EmboSoon"). The need for transfusion and overall technical clinical success (defined as lack of re-intervention) were collected. Length of stay (LOS) and overall mortality, as well as overall morbidity, was evaluated. Pearson chi-square and Wilcoxon Rank-Sum (WRS) analyses were performed on various parameters to determine the significant clinical efficacy of a tiered response system.

RESULTS

A total of 73 trauma activations with EmboNow (n=27) and EmboSoon (n=46) occurred in the study time frame. Of the EmboSoon activations, 28 instances did not require the mobilization of the team and 3 instances required the mobilization of the team but did not progress to intervention. No significant difference was determined when assessing the necessity of hemostatic intervention within the groups. Of the cases requiring embolization (n=31), no difference in the clinical success rate was noted. Overall mortality for the EmboNow and EmboSoon groups was not significantly different, 3.7% and 6.7%, respectively. Also, no significant difference observed between the response groups for average LOS, EmboNow = 10.1 days and EmboSoon = 13.3 days.

CONCLUSION

A tiered response algorithm did not increase overall mortality nor length of stay in patients who ultimately underwent embolization but prevented unnecessary mobilization in 28 cases.

CLINICAL RELEVANCE/APPLICATION

Efficient use of IR resources as well as cooperation and communication among a multidisciplinary trauma team is essential to improve and maintain high-quality clinical services, and to get the best clinical outcomes in management of traumatic hemorrhage.

PURPOSE

To evaluate the added value of the radiomic model in predicting early and late recurrence after resection in a single HCC of less than 5 cm using preoperative gadoxetic acid-enhanced MRI, compared to clinical-only model.

METHOD AND MATERIALS

This retrospective study included 214 patients with surgically resected and pathologically confirmed single HCC (<5cm; 1-2cm [n = 47]; 2-5cm [n = 167]) between January 2010 and December 2015 who underwent preoperative gadoxetic acid-enhanced MR imaging. All prediction models were made with training set and performance was evaluated with temporally independent validation set (training set vs. validation set; 1-5cm, 162 vs 52; 2-5cm, 128 vs. 39). Independent predictors for early and late disease-free survival (DFS) in clinicopathologic information were identified using the Cox regression model, respectively. Three dimensional radiomic features for predicting DFS were selected in each early (<2 years) and late period (2-5 years). A combined radiomic-clinical model (CMB) and a clinical-only model (CLN) were created using a random survival forest and additional values of radiomic features were evaluated using bootstrapping method (n = 1000) in each of the following conditions: early DFS vs. late DFS; tumor size 1-2cm vs. 2-5cm; all combinations of the three dynamic phases (arterial, portal, hepatobiliary phase); the peritumoral border extension included in the radiomic feature extraction (0mm vs. 3mm vs. 5mm).

RESULTS

The combined radiomic-clinical model showed a higher C-index than the clinical-only model in the prediction of early DFS but showed a lower C-index than the clinical-only model in the prediction of late DFS. The combined model using the radiomic features from 2-5cm size tumors, all three phases, 3mm peritumoral border extension showed the highest C-index value (CMB, C-index 0.716 [0.627-0.799]; CLN, C-index 0.696 [0.557-0.799]).

CONCLUSION

Radiomic features combined with clinical factors may improve the prediction of postoperative early recurrence of HCC, but they do not affect the prediction of late recurrence.

CLINICAL RELEVANCE/APPLICATION

Combined analysis of radiomic and clinicopathologic features may influence the postoperative management of patients by increasing the predictive power of postoperative early recurrence of HCC.

SSA07-03 Auto-Encoder and Multilayer Perceptron Assisted Radiomics Approach for Prediction of Early Intrahepatic Recurrence After Radiofrequency Ablation in Hepatocellular Carcinoma

Sunday, Nov. 25 11:05AM - 11:15AM Room: N226

codiwa@gmail.com

PURPOSE

After radiofrequency ablation (RFA), > 50% of early stage hepatocellular carcinoma (HCC) patients undergo intrahepatic recurrence (IHR) within 2-3 years. To optimize the selection of most profitable patients to receive RFA, better prediction algorithms are needed to identify early IHR after RFA. Radiomics allows noninvasively extracting three-dimensional and quantitative features of tumor phenotypes from radiographic images. Recent advances in deep neural network also provide powerful tools for features selection and classification. The present study aims to combine those approaches to establish prediction model to identify patients with a low predicted IHR and suitable for RFA as first-line treatment.

METHOD AND MATERIALS

Patients who initially underwent RFA for single nodular HCC <= 5 cm with Child-Pugh grade A or B were included. A total of 6568 triphasic CT-based features of pretreatment tumors were obtained from 176 patients in the experimental cohort (EC). A Radiomic based prediction model (RPM), trained with variational autoencoder (VAE) and multilayer perceptron (MLP), was developed to predict the 2-year IHR, and validated in an independent validation cohort (VC) of 57 HCC patients. Imaging traits including tumor encapsulation, tumor necrosis, lack of fast wash-in or wash-out, multi-segment involvement were analyzed and correlated to the neurons of the encoder layers as an approach to explain the black box of hidden layers.

RESULTS

The VAE, with 16 neurons in encoder layers, held the task of noise reduction for high dimensional radiomic features, and MLP, with 4 hidden layers, was used to train the model. The RPM, trained with 1,711,457 parameters, outperformed the traditional volumetric predictors of maximal tumor diameter in the prediction of 2-year IHR, with a C-index of 0.757 / 0.707 (EC / VC), compared to 0.540 / 0.510. Imaging traits of tumor necrosis and lack of fast wash-in were associated with neuron_A and neuron_B in the encoder layers. Multivariate analysis showed only RPM and pre-RFA AFP level were significantly associated with 2-year IHF.

CONCLUSION

The radiomics approach provides a novel and convenient way to predict 2-year IHR in patients with early stage HCC who received RFA. The VAE and MLP help denoise high dimensional data and shed the light on the explanation of deep neural network.

CLINICAL RELEVANCE/APPLICATION

The RPM will select most profitable patients to receive RFA

SSA07-04 Development of a Liver Tumor Diagnosis Tool with Deep Neural Networks: Radiologist-Level Performance with Artificial Intelligence

julius.chapiro@yale.edu

PURPOSE

To develop and evaluate the performance of a 3D deep convolutional neural network (CNN) system compared to board-certified radiologists in automatically classifying hepatic lesions on contrast-enhanced multi-phasic magnetic resonance images (MRI).

METHOD AND MATERIALS

This IRB-approved, HIPAA-compliant analysis included 296 patients with a total of 494 focal hepatic lesions of different entities

(simple cyst, hemangioma, focal nodular hyperplasia, hepatocellular carcinoma [HCC], intrahepatic cholangiocarcinoma, and colorectal carcinoma metastasis). Lesions were defined on T1-weighted MRI scans (arterial, portal venous, delayed phase) and divided into training (n=434) and test sets (n=60). The training set was provided to a 3D CNN to learn how to classify each lesion type. The system's performance on the test set was compared with that of two board-certified radiologists.

RESULTS

Over 20 iterations, the CNN model achieved an overall average accuracy of 92%, a sensitivity (Sn) of 92%, and a specificity (Sp) of 98%. The model showed the lowest performance for colorectal carcinoma metastasis (89% Sn, 98% Sp) while the highest performance was achieved in classifying simple cysts (99% Sn, 100% Sp). The model's performance in a single run on the test set showed an average Sn of 90% and Sp of 98% across the six lesion types, compared to an average Sn of 82.5% and Sp of 96.5% for the radiologists. Specifically, the model achieved a 90% Sn for classifying HCC compared to 65% for radiologists. The model showed a true positive rate of 93.5% and false positive rate of 1.6% for HCC classification, with a receiver operating characteristic area under the curve (AUC) of 0.992. The model computation time per lesion was 1 millisecond.

CONCLUSION

This novel 3D CNN system demonstrates the feasibility of AI decision-support to accurately classify several classes of liver lesions on multi-phasic MRI, providing a tool to potentially augment radiologists' performance and efficiency.

CLINICAL RELEVANCE/APPLICATION

As the volume demands of radiology increase, a synergistic workflow that combines a radiologist's experience and intuition with the computational power of AI may enhance efficiency and quality.

SSA07-05 Utility of Radiomics Analysis of Gadoxetic Acid-Enhanced Hepatobiliary Phase MR Images: A Noninvasive Method for Accurate Diagnosis and Staging of Hepatic Fibrosis

Sunday, Nov. 25 11:25AM - 11:35AM Room: N226

Participants
Hyo Jung Park, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose
Seung Soo Lee, MD, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

Jessica Yun, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

happyeahj@gmail.com

PURPOSE

To develop and validate a radiomics-based index for staging liver fibrosis using gadoxetic acid-enhanced hepatobiliary phase (HBP) MR images.

METHOD AND MATERIALS

The institutional review board approved the study, and informed consent was waived. A total of 436 patients with pathologically proven liver fibrosis and gadoxetic acid-enhanced liver MR imaging preceding less than 3 months of histopathologic analysis were included (132, 22, 53, 77, 153 for fibrosis grade 0, 1, 2, 3, 4, respectively). The subjects were randomly divided into the development and test cohorts at a ratio of 3:1. Feature extraction was performed from HBP images, and extracted features included 8 histogram features and 35 high-order textural features. For feature selection and modeling for binary decision to discriminate F0-2 vs. F3-4, we used a logistic regression with elastic net regularization. Performance of the selected model in diagnosing significant fibrosis (>= F2), advanced fibrosis (>= F3), and cirrhosis (F4) was evaluated using the AUROC in the test cohort, and was compared with serum markers (APRI and FIB-4).

RESULTS

Radiomic fibrosis index had significant positive correlation with the pathologic fibrosis stage (ρ=0.735, P<.001). In the test cohort, AUROCs of the model were 0.9, 0.89, and 0.91 for diagnosing significant fibrosis, advanced fibrosis and cirrhosis, respectively. The Obuchowski index, a weighted average of the AUROC values obtained for all pairs of fibrosis stages, was 0.864 (62% CI, 0.819-0.909) in radiomics model, significantly higher than those of APRI (0.604, P<.001) and FIB-4 (0.621, P<.001). Using the threshold values for radiomic fibrosis index determined in the development cohort, the sensitivities of 78.9% - 92.1%, specificities of 75.4% - 82.0%, and accuracies of 80.3% - 81.3% were achieved for diagnosing significant fibrosis, advanced fibrosis, and cirrhosis in the test cohort.

CONCLUSION

Radiomics analysis of HBP images of gadoxetic acid-enhanced MRI can provide accurate diagnosis and staging of liver fibrosis.

CLINICAL RELEVANCE/APPLICATION

Radiomics analysis of HBP images has a potential usefulness for the noninvasive and accurate diagnosis and staging of hepatic fibrosis.

SSA07-06 Application Value of Radiomics Features Based on Monochromatic Images of Spectrum CT in the Pathological Grading of Gastric Adenocarcinoma

PURPOSE

To evaluate the clinical value of radiomics features based on monochromatic images of spectrum CT in the pathological grading of gastric adenocarcinoma.

METHOD AND MATERIALS

Retrospectively 196 patients with gastric adenocarcinoma who underwent upper or total abdominal GSI scanning using the Discovery 750 CT machine were collected, who were divided into poorly differentiated group (Group A) and moderately-well differentiated group (Group B) according to pathological results. High-quality, standardized venous phase single-energy images of 70 keV were obtained from the AW4.6 workstation, and then radiomics features based on the monochromatic images were extracted and a Logistic regression model was established by the dimensionality-reduced features.The efficacy of the Logistic regression model was evaluated by the receiver operating characteristic curve (ROC) and its accuracy was verified. At the same time, the grading results and performance of conventional energy spectrum parameters were compared and analyzed.

RESULTS

The grading efficacy of the normalized iodine (water) concentration of conventional spectral parameters was 0.668. The area under the ROC curve (AUC) of the Logistic regression model was 0.872 (sensitivity was 73.3% and specificity was 83.3%) and the diagnostic accuracy was 78.3%.

CONCLUSION

Radiomics features based on the single-source dual-energy CT monochromatic images can non-invasively differentiate gastric adenocarcinoma from poorly differentiated and moderately-well differentiated tumors. Its efficacy is better than that of conventional spectral CT.

CLINICAL RELEVANCE/APPLICATION

Radiomics features based on the single-source dual-energy CT monochromatic images can provide more quantitativeand repeatable information for clinical treatment options and preoperative evaluations.

SSA07-07 Multi-Feature Based CT Radiomic Signature Peroperatively Predicts Lymph Node Metastasis in Advanced Gastric Cancer

fmj5mj@gmail.com

PURPOSE

To investigate whether the method of deep learning could improve the performance of radiomic features, and to build a radiomic signature for preoperative prediction of lymph node metastasis (LNM) in patients with advanced gastric cancer (AGC).

METHOD AND MATERIALS

In this ethical-approved retrospective study, we collected a primary cohort consisting of 110 patients from Center 1 and a validation cohort consisting of 121 patients from Center 2. A total of 521 features were extracted from venous-phase CT images. The features could be divided into two groups: deep learning features and conventional hand-crafted features. Based on the whole feature set and the hand-crafted-only feature set respectively, RELIEFF and support vector machine model were implemented to select key features and build two radiomic signatures to yield quantitative risk for LNM. The predictive performances of the signatures were evaluated by receiver operator characteristics analysis and accuracy analysis in the external validation cohort.

RESULTS

Combining the deep learning features and conventional features, the multi-feature based CT radiomic signature outperformed the conventional signature (area under the curve: 0.799 vs. 0.735 in the external validation cohort). It showed powerful predictive ability of discriminate non-N0 patients from N0 patients with accuracies of 0.764 (95% confidence interval [CI]: 0.673-0.839) and

0.736 (95% CI: 0.648-0.812) in the primary and validation cohorts respectively.

CONCLUSION

Taking advantages of the novel deep learning method and the conventional machine learning method, radiomic signature could serve as a useful tool for preoperative LNM status prediction in patients with AGC.

CLINICAL RELEVANCE/APPLICATION

Multi-feature based CT radiomic signature has potential in the preoperative non-invasive prediction of lymph node metastasis and facilitate the clinical strategy.

SSA07-08 Correlation Analysis of Spectral CT Parameters and K-ras Gene Mutation in Colorectal Cancer

Sunday, Nov. 25 11:55AM - 12:05PM Room: N226

Participants
Dan Wang, Lanzhou, China (*Presenter*) Nothing to Disclose
Junlin Zhou, Lanzhou, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the relationship between K-ras mutation of colorectal cancer and the quantitative parameters and qualitative parameters with spectral CT.

METHOD AND MATERIALS

A retrospective analysis of 66 cases of colorectal adenocarcinoma with K-ras mutation confirmed by surgical or endoscopic biopsy was performed by spectral CT dual-phase enhanced scans. The relationship between K-ras mutation and the qualitative and quantitative parameters of CT was statistically analyzed. The CT qualitative evaluation included the location of the tumor, the thickening of the intestinal wall, the infiltration of perienteral fat, and the enlargement of the lymph nodes; the parameters of the CT quantitative assessment include the 40~140keV single energy CT, the iodine (water) concentration, the water(iodine) concentration,the normalized iodine concentration(NIC) and the spectrum curve slope in the arterial and venous phase. The slope is calculated according to the following formula: slope = (CT40keV-CT100keV) /60. Chi-square test was used to statistically analyze the correlation between CT qualitative signs and K-ras mutation status. Independent sample t-test was used for statistical analysis to evaluate the correlation between spectral CT features and K-ras mutations.

RESULTS

K-ras mutations were positive in 32 (48%) of the 66 patients. The colorectal cancer patients with K-ras mutation were multiple in the right hemicolon(x2=8.09,P=0.007), eccentric thickening(x2=12.17,P=0.001), and more perienteric lymph nodes(x2=12.17,P=0.001), which were not related to the degree of fat infiltration around the lesions, and the extent of perianal invasion(P>0.05). The iodine concentration(t=-3.47,P=0.002) , NIC(t=-3.18,P=0.004) , the slope of the spectrum curve(t=-3.58,P=0.001) and the CT value of the low energy level (40-70 keV) (P<0.05) in arterial phase were increased in the K-ras mutation-type colorectal cancer patients than the wild-type ones.

CONCLUSION

K-ras mutations in colorectal cancer correlated with a part of spectral CT quantitative parameters and qualitative parameters.

CLINICAL RELEVANCE/APPLICATION

K-ras mutations could be initially judged by qualitative and quantitative parameters of spectral CT.

SSA07-09 MRI-Based Radiomics Analysis for Predicting KRAS Mutation in Patients with Rectal Cancer

Sunday, Nov. 25 12:05PM - 12:15PM Room: N226

Participants

For information about this presentation, contact:

liuhuanhuan0117@163.com

PURPOSE

Genetic profiling of tumors is important for personalized treatment through the development of targeted therapies. For patients with suspected or proven metastatic rectal cancer, the identification of KRAS/NRAS/BRAF mutations is of great significance. Either of the mutations predicts a lack of response to cetuximab and panitumumab, which is important for the individual treatment strategy. Therefore, our study was to investigate the value of radiomics analysis for predicting KRAS mutation in patients with rectal cancer.

METHOD AND MATERIALS

A total of 128 patients with histopathologically confirmed rectal cancer who underwent preoperative MR imaging and postoperative KRAS mutation test without any preoperative chemoradiotherapy were divided into the primary cohort (n=89) and the validation cohort (n=39). MRI-based radiomics features were extracted from oblique axial T2-weighted images. The independent two-sample t test, Kruskal-Wallis test, and Pearson correlation analysis were used for features selection. A radiomics signature was built and multivariable logistic regression analysis was used to develop the radiomics model including radiomics features and independent clinico-radiologic risk factors. The performance of the radiomics model was assessed by the receiver operating characteristic curve (ROC) and decision curve analysis.

RESULTS

A total of 385 radiomic features were extracted from each patient, and 12 radiomics features were selected for the radiomics signature. The radiomics signature was significantly associated with KRAS mutation (P<0.001). The areas under the ROCs were 0.845 in the primary cohort and 0.767 in the validation cohort. Decision curve analysis confirmed the clinical utility of the radiomics model. The clinical background and tumor MRI-staging showed no significant correlation with KRAS mutation.

CONCLUSION

The MRI-based radiomics model could be used to predict the KRAS mutation in patients with rectal cancer, which could be helpful for individual treatment strategy.

CLINICAL RELEVANCE/APPLICATION

(dealing with MRI-based radiomics) "The MRI-based radiomics model could be used to predict the KRAS mutation in patients with rectal cancer, which could be helpful for individual treatment strategy"

PURPOSE

Diffusion-weighted-imaging (DWI) is increasingly used for Crohn's disease (CD) evaluation. Sensitivity and specificity rates are however heterogeneous1-5, and only two series to-date reported paediatric CD results4,6. We report one of the largest series for DWI evaluation of adult and pediatric CD.

METHOD AND MATERIALS

Between 2014 and 2016, 77 patients (18 pediatrics) underwent DWI for CD. All had histopathological confirmation within 28 days. Two radiologists were presented random DWI sequences, to evaluate bowel segments for disease activity, based subjectively on "greater-than-normal visual diffusion-restriction", followed objectively by mean minimum-ADC values. Sensitivity/specificity for detection and inter-observer reliability were recorded. Differences in ADC values calculated with unpaired t-test.

RESULTS

Both radiologists had 99% sensitivity and specificity (kappa 0.98) in terminal ileitis detection. Minimum mean ADC values were 1.3±0.4×10-3mm2/s. Overall specificity rates of 75% in determining colonic involvement. The greatest disparity was within the sigmoid, with 68% specificity. Moderate inter-observer reliability achieved (kappa 0.40). ADC values significantly differed between true and false positive colonic segments (Mean ADC 1.08±0.4×10-3mm2/s vs. 1.84±0.55×10-3mm2/s, p<0.0001). Overall results were similar for the pediatric subgroup.

CONCLUSION

We achieved a 99% diagnostic rate of CD affected terminal ileum. Low specificity and interobserver reliability for CD affected colon, however, ADC quantitative values improved diagnostic accuracy and correlation.

SSA08-02 High Spatiotemporal Resolution Free-Breathing Quantitative Bowel Perfusion Imaging

PURPOSE

This study shows that 3D through-time spiral GRAPPA can be used to acquire DCE-MRI data of the bowel with a high spatiotemporal resolution without a need for breath-holding, and enables quantitative perfusion analysis of the entire bowel.

METHOD AND MATERIALS

3D DCE-MRI data of the bowel was obtained from 7 patients with Crohn disease undergoing MRE exam at 1.5T (Siemens Aera). A total of 50 coronal volumes were acquired continuously over the course of approximately 1.5 minutes after the injection of 0.1 mmol/kg gadobenate dimeglumine (3ml/s) with a temporal resolution of 1.6s while the patients breathed freely. Each volume included 40 slices with an in-plane matrix size of 272×272, in-plane resolution of 1.5 mm, and an uninterpolated slice thickness of 4 mm. Conventional qualitative MRI findings were recorded. The Tofts model was used to quantitatively characterize contrast enhancement in the bowel. Multislice ROIs were drawn in the bowel wall as well as in the aorta to calculate the arterial input function. Ktrans and ve were quantified by fitting the mean signal within each ROI from the bowel to the model.

RESULTS

This acquisition technique allowed for full coverage of the entire abdomen. Mean age was 40.1 years (range 19-68 years) in 3 male and 4 female patients. 2 showed active inflammatory changes while 5 did not exhibit evidence of active disease at the time of examination. All inflamed bowel segments showed mural thickening and increased contrast enhancement. Quantified perfusion properties for segments with active inflammation were in mean 0.096±0.045 (0.044-0.123) compared to non-affected segments 0.019±0.033 (0.002-0.099) for Ktrans and 0.476±0.212 (0.337-0.724) vs. 0.223±0.319 (0.068-0.232) for ve.

CONCLUSION

This study shows that free-breathing, high spatiotemporal resolution, and quantitative 3D DCE-MRI of the bowel is feasible with spiral GRAPPA leading to accurate characterization of the early arterial portions of the bowel contrast enhancement time course. Although evaluated in a limited number of patients, perfusion metrics already demonstrate separation of normal and inflamed bowel wall.

CLINICAL RELEVANCE/APPLICATION

Spiral GRAPPA allows for quantitative perfusion assessment of the intestine without preselecting specific loops as the entire abdomen is covered. This sequence can be used for future therapy response assessment trials.

SSA08-03 Tagged Cine-MRI for the Assessment of Caloric Stimulation of Small Bowel Motility

Sunday, Nov. 25 11:05AM - 11:15AM Room: N227B

Participants
Catharina S. de Jonge, MSc, Amsterdam, Netherlands (*Presenter*) Nothing to Disclose
Andre M. Sprengers, PhD, Nijmegen, Netherlands (*Abstract Co-Author*) Nothing to Disclose
Kyra L. van Rijn, MD, Amsterdam, Netherlands (*Abstract Co-Author*) Nothing to Disclose
Aart J. Nederveen, PhD, Amsterdam, Netherlands (*Abstract Co-Author*) Nothing to Disclose
Jaap Stoker, MD, PhD, Amsterdam, Netherlands (*Abstract Co-Author*) Research Consultant, Robarts Clinical Trials, Inc

PURPOSE

Continuously tagged imaging for the assessment of motility in the small bowel region has been demonstrated as an alternative to other more established MRI techniques. Providing its own contrast and the possibility to monitor motility during free-breathing, this technique can assess motility at frequencies as low as 2 contractions per minute (cpm), this is the slow wave, motility pattern range. This study aims to validate a clinically feasible test for small bowel motility assessment in the low frequency range using tagged cine-MRI before and after a 300-kCal meal.

METHOD AND MATERIALS

After ±11h overnight fasting, 16 healthy subjects (9 males, median age 25, range 19-37y) underwent a free-breathing, tagged cine-MRI to capture global small bowel motility. Each subject underwent i) baseline motility scan ii) food challenge with Nutridrink iii) post-challenge scan iv) second post-challenge scan (after ±20 minutes). Motility was quantified within a region of interest covering the small bowel, using a validated frequency analysis technique for measuring the spectral power of the strain, referred to as 'motility score'. Motility score was assessed in 20 frequency intervals between 1-20 cpm.

RESULTS

The motility score was consistently higher in the low frequency regime (1-10cpm) right after caloric intake, this regime is consistent with the stomach and bowel frequencies (3-12 cpm). The difference between baseline motility score and directly after drinking was significant in the low range intervals 2-4cpm and 6-8cpm. The difference between the motility score directly after drinking and ±20 minutes after drinking was significant in the low range intervals 1-4cpm. No significant changes were observed in the breathing range.

CONCLUSION

This study demonstrates the continuously tagged imaging sequence and quantification method is capable of assessing changes in motility patterns in high detail during free breathing. The method is non-invasive and independent of preparation, enabling monitoring in both fasted and fed state. This indicates that it can be used to perform stimulation tests to measure response in various frequency intervals and with that assess (patho)physiology in the gastrointestinal tract.

CLINICAL RELEVANCE/APPLICATION

Continuously tagged MR imaging is capable of non-invasively assessing small bowel motility in high detail during free breathing, providing a tool to explore (patho)physiology in fasted and fed state.

SSA08-04 Value of Spectral Computed Tomography Imaging For Evaluation of Intestinal Activity and in Crohn's Disease

PURPOSE

To investigate the clinical value of spectral CT imaging in assessing the activity of Crohn's disease compared with the simple endoscopic score (SES).

METHOD AND MATERIALS

50 patients suspected to have Crohn's disease received both colonoscopy and contrast enhanced computed tomographic enterography (CTE) were involved in this study.The interval time between the two examinations was less than one week. All patients were scanned on a GE Discovery 750 HDCT scanner using GSI spectral imaging mode.The portal-phase monochromatic images from 40 to 140kev and iodine-based material decomposition images were reconstructed after scan. Reconstructed images data were processed with GSI Viewer for analysis. According to the SES-CD (Simple Endoscopic Score for Crohn's Disease)scores,50 patients were divided into 4 groups(GroupA:Score=0-2,n=6;GroupB:Score=3-6,n=12;GroupC:Score=7-15,n=17;GroupD:Score>=16,n=15).Three different locations of suspicious area of the small bowel were selected from each patient.The spectral curve slope and its mean value were calculated under 40-70KeV;the iodine concentrations and effective atomic number of the involved bowel wall in material decomposition images were measured; the CT value of 50KeV images were measured;the variance analysis was used for the iodine concentration and spectral curve slope comparison among the four groups.

RESULTS

The spectral curve slopes(-1.58±0.48,-2.17±0.66,-3.18±1.07,-3.97±0.65)and iodine concentrations (8.02±1.70,12.33±2.23,17.84±4.40,22.24±3.61),CT value of 50 KeV (60.41±1.60,72.67±3.23,111.66±4.21,140.57±4.01)and effective atomic number (7.78±0.07,8.12±0.09,8.45±1.21,8.77±1.01)of four groups were found statistically significant different (P<0.01);the spectral curve slopes,iodine concentrations,CT value of 50KeV,effective atomic number among Group A,Group C and Group D were statistically different(P<0.05);Group B,Group C and Group D were statistically different(P<0.05).

CONCLUSION

The spectral curve slope,the iodine concentration,the CT value of 50KeV and effective atomic number of the small bowel derived from spectral CT imaging can be used to evaluate the activity of Crohn's disease.

CLINICAL RELEVANCE/APPLICATION

Spectral CT had sensitivity in detecting intestinal activity and severity of CD,which could be an alternative choice in evaluation of CD.The purpose of this study was to establish the standards of evaluating the activity of Crohn's disease using spectral CT in the future.

SSA08-05 Eliminating Unnecessary Anatomic Coverage Allows for Significant Radiation Dose Savings in Follow-Up Outpatient CT Enterographies of Young Crohn's Adults

Sunday, Nov. 25 11:25AM - 11:35AM Room: N227B

Awards
Student Travel Stipend Award

Participants
David C. Wang, MD, Toronto, ON (*Presenter*) Nothing to Disclose
Sarah A. Johnson, MD, Toronto, ON (*Abstract Co-Author*) Nothing to Disclose
Nasir M. Jaffer, MD, Toronto, ON (*Abstract Co-Author*) Nothing to Disclose
Luis S. Guimaraes, MD, Toronto, ON (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To determine the minimal Z-axis coverage necessary to include all relevant extra-intestinal (EI) findings and the entire bowel in follow up CT enterographies (CTEs) of young Crohn's (CD) outpatients, and the potential radiation dose savings in eliminating unnecessary Z-coverage in this young population, where significant EI findings are rare and dose savings are beneficial.

METHOD AND MATERIALS

All outpatient CTEs of 18-40 years old CD patients performed from January to December 2016 were included. Two abdominal radiologists in consensus noted the most inferior vertebral level - superior endplate (SE) - that would include: 1) entire small bowel (SB), 2) all diseased SB, 3) all diseased colon, and 4) EI findings. Total Z-axis coverage and the distance from the top of the scan to each SE was measured. The percentage of potential dose savings based on the percentage of unnecessary Z-axis coverage was calculated.

RESULTS

80 scans were included. All diseased colon and the entire SB was always inferior to the SE of T12. All diseased SB segments were inferior to L2. 9% had potentially significant EI findings: 1 pneumonia (T11), 1 focal biliary dilatation (T12), 2 chronic mesenteric venous thrombosis (L1 and L3), 2 sacroiliitis (S1) and 1 peripheral nerve sheath tumor (S5). However, only the pneumonia had management implications. Mean dose savings - with standard deviation (SD) and confidence intervals (CI) - achieved by starting the scan at T12, L1 and L2 would be 15.3% (SD: 4.1, 95%CI: 14.5 - 16.2), 21.5% (SD: 3.9; 95% CI: 20.6 to 22.4) and 28.4% (SD: 3.6; 95% CI: 27.6 - 29.2), respectively.

CONCLUSION

L2 was the cutoff to include all diseased small bowel segments, creating a potential for mean dose savings of 28% in this population. While T12 was the cutoff to include the entire SB (dose reduction of 15%), new proximal SB disease on follow up scans is very rare and was never found above L2 in our population. T12 was also the cutoff that included all EI findings except a

pneumonia, with no additional clinically significant EI findings above L2. There is an opportunity for 15-28% mean dose reduction on CTEs just by excluding unnecessary anatomic coverage.

CLINICAL RELEVANCE/APPLICATION

In a population that particularly benefits from dose reduction (young Crohn's adults), the dose of follow-up CTEs can be significantly reduced by eliminating unnecessary anatomic coverage.

SSA08-06 Evaluation of Bowel Fibrosis in Crohn's Disease Combining Diffusion Kurtosis and Intravoxel Incoherent Motion MR Imaging: Correlation with Surgical Histopathology

guitar_sun@163.com

PURPOSE

To assess the utility combining diffusion kurtosis imaging (DKI) and intravoxel incoherent motion (IVIM) Imaging for grading the degrees of the intestinal fibrosis in Crohn's disease (CD), using surgical histopathology as the reference standard.

METHOD AND MATERIALS

21 CD patients underwent both elective surgery and diffusion weighted imaging (b values of 0-2000 s/mm2). Apparent diffusion coefficients (ADCs) was calculated using b values of 100-1000 s/mm2. Diffusion coefficients (Dapp) and kurtosis (Kapp) on DKI maps (b values of 0, 600, 1000, 1500 and 2000 s/mm2) and pesudodiffusion coefficient (D*) and perfusion fraction (f) on IVIM maps (b values of 0,10, 20, 40, 60, 80, 100, 150, 300, 600 and 1000 s/mm2) were measured region-by-region with surgical specimens. Resected bowel tissues were scored from 1 to 3 for histologic fibrosis.The parameters f, ADCs, and Kapp were combined to provide a single diagnostic grade compared with the fibrosis score.

RESULTS

67 surgical specimens were evaluated and included none-mild (n=28), moderate (n=21) and severe (n=18) fibrosis. Significant differences were found between none-mild and both moderate and severe fibrotic segments for ADCs, Dapp, Kapp and f (P<0.05). They had similar correlation with histologic fibrosis scores (r: 0.644 for Kapp, -0.522 for Dapp, -0.635 for f, -0.601 for ADCs, all P<0.05). D* did not correlate with histological fibrosis. High accuracy for differentiating moderate-severe fibrotic from none-mild fibrotic segments (AUC: 0.826 for Kapp, 0.791 for Dapp, 0.860 for f, 0.806 for ADCs) was showed by ROC analysis and the thresholds of 0.336 for f, 1.177 mm2/s for ADCs and 0.787 for Kapp were found with sensitivity of 92.61%, 84.6% and 89.7%, and specificity of 82.50%, 71.4%, 75%, respectively. The integrated score combined f, ADCs and Kapp thresholds was found a good correlation with histological fibrosis (r: 0.817, P<0.05). And AUC for differentiating moderate-severe fibrotic from none-mild fibrotic segments was 0.889 (P<0.001) with 94.40% sensitivity and 85.21% specificity.

CONCLUSION

DKI and IVIM can both detect varying degrees of bowel fibrosis in CD. Combination of DKI and IVIM parameters appears to improve diagnostic accuracy and the performance was better than single parameter of DKI or IVIM.

CLINICAL RELEVANCE/APPLICATION

Combination of DKI and IVIM parameters appears to improve diagnostic accuracy compared with single parameter for detecting bowel fibrosis in CD.

SSA08-07 Comparison of Three Magnetization Transfer Ratio Parameters for the Assessment of Bowel Wall Fibrosis in Crohn's Disease

Sunday, Nov. 25 11:45AM - 11:55AM Room: N227B

Participants
Jixin Meng, Guangzhou, China (*Presenter*) Nothing to Disclose
Xuehua Li II, Guangzhou, China (*Abstract Co-Author*) Nothing to Disclose
Siyun Huang, MD, Guangzhou, China (*Abstract Co-Author*) Nothing to Disclose
Mengchen Zhang, Guangzhou, China (*Abstract Co-Author*) Nothing to Disclose
Canhui Sun, MD, PhD, Guangzhou, China (*Abstract Co-Author*) Nothing to Disclose
Ziping Li, MD, PhD, Guangzhou, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Magnetization transfer ratio (MTR) and normalized MTR derived from MT-MRI has been reported as two promising parameters to quantitatively detect bowel fibrosis in Crohn's disease (CD). However, the use of these two parameters for grading bowel fibrosis has not consider the presence of slightly increasing MTR in normal bowel wall due to the existence of intestine smooth muscle. Hence, we establish a new MTR index which includes the element from normal bowel wall. The aim of this study was to compare the efficacy of the three MTR indices for the assessment of bowel wall fibrosis in CD and then select an optimal index for the clinical application, using surgical histopathology as the reference standard.

METHOD AND MATERIALS

Abdominal MT imaging of 20 consecutive CD patients were analyzed before selective operation. The MTR, normalized MTR (MTR in

Abdominal MR imaging of 20 consecutive CD patients were analyzed before subjective operation. The MTR, normalized MTR (MTR in affected bowel wall÷MTR in skeletal muscle), and new MTR ([MTR in affected bowel wall-MTR in normal bowel wall]÷ [MTR in skeletal muscle- MTR in normal bowel wall]) were calculated. Region-by-region correlations between MT imaging and surgical specimen were performed, and Masson staining was using to manifest the histologic degree of fibrosis. Spearman rank correlation, one-way ANOVA test, and receiver operating characteristic curve were used for statistical analysis.

RESULTS

63 fibrotic intestinal segments from 20 CD patients were included in this study. Normalized MTR showed the strongest correlation with bowel fibrosis score (r=0.700,P <0.001), followed by new MTR (r=0.695,P<0.001) and MTR (r=0.590,P<0.001). The significant differences in MTR (F=23.13,P<0.001), normalized MTR (F=21.073,P<0.001) and new MTR (F=10.577,P<0.001) were found among mild, moderate and severe bowel fibrosis, respectively. MTR (AUC=0.959, P<0.001) and normalized MTR (AUC=0.933, P<0.001) had similar accuracy for differentiating moderate-severe from mild bowel fibrosis, followed by new MTR (AUC=0.883, P=0.002).

CONCLUSION

MTR, normalized MTR and new MTR are all able to detect and grade intestinal fibrosis in CD. Normalized MTR may be slightly superior to both MTR and new MTR and be an optimal index to quantitatively reflect the severity of bowel fibrosis with a simple calculation.

CLINICAL RELEVANCE/APPLICATION

The normalized MT ratio might be the relatively preferable indicator for assessing intestinal fibrosis in CD patients, which contributes to guiding further clinical treatment.

SSA08-08 Natural History of Inflammatory Strictures in Small Bowel (SB) Crohn's Disease in the Setting of Anti-TNF Therapy

fletcher.joel@mayo.edu

PURPOSE

To examine the natural history of Crohn's small bowel (SB) strictures, examining both the need for subsequent surgery as well as their development from active inflammation, in Crohn's disease (CD) patients treated with anti-TNF therapy.

METHOD AND MATERIALS

Adult CD patients with SB strictures (luminal narrowing + proximal SB dilation) underwent serial CTE/MRE during anti-TNF therapy. Every stricture was examined by a GI radiologist for the severity of inflammation with associated imaging findings, penetrating disease, and other complications. Numerous morphological measurements were obtained (wall thickness, length, proximal SB dilation), and various ratios of these measurements were calculated. Patients were categorized into groups based on time of stricture development (baseline CTE/MRE vs. subsequent) and surgical outcome (surgical resection vs. observation).

RESULTS

58 CD patients (age 44±15; 27 females) with 74 strictures underwent CTE/MRE (47/11). 39 strictures (33 patients) underwent surgery (mean time of 2.7years) and 35 strictures (25 patients), who were observed for a mean of 5.3 years. Strictures going to surgery were associated with enteric fistulas [38% (15/39) vs. 11% (4/35)], perienteric edema [44%(17/39) vs. 23%(8/35)], and chronic mesenteric vein occlusion [12%(4/33) vs. 4%(1/25(4%)]. Stricture morphologic measurements and ratios were similar among the surgery and observation groups. There were 57 strictures (42 patients) at baseline and 17 strictures (16 patients) that developed on subsequent exams. Prior to stricture development, involved SB segments had less pronounced wall thickness (5.5 vs.7.8 mm), length of involvement (9.6 vs. 12.4 cm), and less inflammation compared to appearance at time of stricture development. New strictures had less pronounced wall thickness (7.8 vs. 9.2mm) and less penetrating disease [6% (1/17) vs. 35% (20/57)] than established strictures.

CONCLUSION

Strictures undergoing subsequent resection were associated with penetrating disease, perienteric edema, and mesenteric vein occlusion. Development of strictures from inflamed segments and subsequent development of penetrating complications is consistent with current concepts of CD progression.

CLINICAL RELEVANCE/APPLICATION

Strictures associated with penetrating disease, perienteric inflammation, and mesenteric vein occlusion are more likely to undergo surgery.

sean@arterys.com

PURPOSE

To develop an automated deep learning-based method for liver lesion segmentation on MRI scans in order to enable more efficient quantification of lesion size and measurement of growth over time.

METHOD AND MATERIALS

We utilize 1,312 annotated lesions from 607 unique abdominal MRI studies and 393 unique patients. DICOM images and lesion locations were collected as part of standard clinical care. Identified lesions were segmented manually on multiphasic contrast-enhanced series by annotators trained in liver lesion segmentation. The median lesion diameter was 15.8 mm, while the median lesion volume was 1.469 mL. We designate an 80%-10%-10% split between the training, validation, and testing sets. We report all metrics on the test set. We use a fully-convolutional neural network that operates on 3D patches, centered on the lesion of interest. The network is a variant of the ENet segmentation architecture.

RESULTS

Our automated contouring method achieved a median volume error of 0.277 mL and a median LLD error of 2.01 mm. The median LLD error is significantly below the LI-RADS 'threshold growth' threshold (5.0mm).

CONCLUSION

Our automated lesion segmentation method yields a low median LLD error, demonstrating that our estimates may be used as part of a semi-automated clinical workflow in which the clinician may review and modify the segmentations. Additionally, we demonstrate that automated volumetric estimates are feasible from MRI and, with further validation, may provide a viable method of tracking tumor volume over time.

CLINICAL RELEVANCE/APPLICATION

An automated liver lesion segmentation system may improve radiologist accuracy and efficiency in quantifying lesion size and measuring growth over time.

SSA09-03 Convolutional Neural Networks Permit Estimation of Whole-Liver Hepatic Proton-Density Fat Fraction from Single or Dual-Echo Chemical-Shift-Encoded MRI

PURPOSE

Confounder-corrected, chemical-shift-encoded (CSE) MRI with 6-echo acquisitions accurately quantifies hepatic proton-density fat fraction (PDFF). However, 6-echo acquisition increases scan time, might result in motion artifact, and limits image resolution of PDFF maps. This study assessed the feasibility of estimating PDFF from the first echo or first 2 echoes of 6-echo CSE MRI using a convolutional neural network (CNN).

METHOD AND MATERIALS

In this IRB-approved and HIPPA-compliant study, we retrospectively identified 355 liver 3T MR exams that included a magnitude-based PDFF sequence comprising 6 gradient-echo images at sequential nominally out- and in-phase echo times. A non-linear fitting algorithm was used to reconstruct the PDFF maps pixel-by-pixel (6-echo PDFF). Using 310 image datasets selected at random, we trained a CNN to estimate 6-echo PDFF maps using only the first echo (1-echo PDFF) or the first two echoes (2-echo PDFF). We tested the CNN in the other 45 PDFF acquisitions. On each axial image containing liver, the liver was segmented and the average PDFF values across all liver pixels was calculated. Per-image mean hepatic 1-echo PDFF and 2-echo PDFF were compared with 6-echo PDFF using Pearson correlation and Bland-Altman analyses.

RESULTS

A total of 1065 images were analyzed. Per-image 6-echo PDFF values ranged from 0% to 43%, while R2* ranges from 33 to 195 s-1. Correlations were high for 1-echo vs. 6-echo PDFF (R2=0.99, slope=0.96, intercept=-0.04) and for 2-echo vs. 6-echo PDFF (R2=0.99, slope=0.98, intercept = 0.29). Compared to the the 6-echo method, the 1-echo method showed minimal PDFF overestimation (bias of 0.56%, $p<0.01$) while the 2-echo method showed minimal PDFF underestimation (bias = -0.12%, $p<0.001$); 95% limits of agreement were [-1.3%,2.4%] for 1-echo and [-1.15%, 0.91%] for 2-echo PDFF.

CONCLUSION

A CNN can accurately estimate hepatic PDFF from either the first or first two echoes of a magnitude-based CSE PDFF sequence in livers without substantial iron overload. Further work is required to determine whether these results are generalizable for other pulse sequences, scan parameters or concurrent pathology.

CLINICAL RELEVANCE/APPLICATION

CNN-based whole-liver PDFF estimation from single or two-echo acquisitions might reduce scan time and enable broader clinical use of quantitative fat fraction measurement.

SSA09-04 A New Multi-Model Machine Learning Framework to Improve Hepatic Fibrosis Grading Using Ultrasound Elastography Systems from Different Vendors

Sunday, Nov. 25 11:15AM - 11:25AM Room: N228

durot@stanford.edu

PURPOSE

To show that the diagnostic performance of point shear wave elastography (pSWE) and two-dimensional shear wave elastography (2DSWE) for grading liver fibrosis using shear wave velocity (SWV) combined with a new machine learning (ML) technique, can be as accurate as magnetic resonance elastography (MRE) and can be applied to ultrasound systems from different vendors.

METHOD AND MATERIALS

This IRB-approved retrospective study included two patient groups with chronic liver disease: 1) 123 patients undergoing pSWE (Siemens S2000) and MRE; and 2) 60 patients undergoing 2DSWE (Philips Epiq7) and MRE. For Siemens data, accuracy of median SWV to differentiate clinically non-significant from significant fibrosis was calculated using the published cutoff value of 1.34 m/s, with MRE-based fibrosis grading used as the standard. Next, for both groups, in a technique not using any published US elastography cutoff values, median SWV and true labels from MRE-based grading were input to the Matlab perfcurve function to generate a receiver-operating characteristic (ROC) curve and calculate area-under-the-curve (AUC). Finally, in both groups, four ML algorithms - support vector machines (SVM), logistic regression, naïve Bayes, and quadratic discriminant analysis - using ten SWV measurements as inputs were trained with MRE as the gold standard to obtain MRE-equivalent binary fibrosis grading; scores from the ML algorithms were input into the Matlab perfcurve function to generate ROC AUC, and results were validated using two-fold cross validation.

RESULTS

The performance of median SWV to differentiate clinically non-significant and significant fibrosis (with MRE as the gold standard) was fair for pSWE with the published cutoff value for Siemens (accuracy 55.4%); moderate for Siemens (AUC: 0.73) and Philips (AUC: 0.71) without using a cutoff value; and excellent for an SVM ML algorithm in both groups (Siemens: AUC: 0.96; Philips: AUC: 0.97).

CONCLUSION

The results from Siemens and Philips data suggest that a multi-vendor ML-based algorithm can grade liver fibrosis using ultrasound elastography with excellent diagnostic performance, comparable to MRE. SVMs outperformed the current standard of assessment, median SWV.

CLINICAL RELEVANCE/APPLICATION

The new ML algorithm may be applied to systems from different vendors after validation, providing more comparable and accurate fibrosis grading.

PURPOSE

To establish a fully automatic 3D deep learning liver segmentation-system for contrast-enhanced liver MRI.

METHOD AND MATERIALS

Data-sets of Gd-EOB-DTPA-enhanced liver MR images of 100 patients have been selected. The ground truth segmentation of the liver parenchyma in the hepatobiliary phase was performed manually by a resident physician with five years of experience. The dataset was split into a training/validation set (n = 75) and a testing set (n = 25). The artificial neural network (ANN) used in this study is based on 3D-Unet (Cicek et al. 2016, arxiv: 1606.06650). The trained ANN was used to perform a fully automatic image segmentation of the testing set.

RESULTS

The ANN accomplishes a Dice index of 95.1±2.3 % (mean±std), an overlap of 90.8±3.9 % and a volume difference of 3.8±6.8%.

CONCLUSION

This study demonstrates a 3D neural network, which is able to provide a fully automatic segmentation scheme for MRI Images. It is able to segment the liver parenchyma with high precision.

CLINICAL RELEVANCE/APPLICATION

The 3D neural network provides an accurate automatic liver segmentation in MRI; hence it would serve as a useful tool for

radiologists for treatment planning, especially for patients undergoing liver surgery.

SSA09-06 Machine Learning for Rapid Assessment of Outcomes of an Ultrasound Screening and Surveillance Program in Patients at Risk for Hepatocellular Carcinoma

Sunday, Nov. 25 11:35AM - 11:45AM Room: N228

hailey.choi@ucsf.edu

PURPOSE

To determine large-scale retrospective outcomes of surveillance ultrasound exams in high-risk populations according to the American College of Radiology (ACR) Ultrasound Liver Imaging Reporting and Data System (LI-RADS) classification.

METHOD AND MATERIALS

13,860 ultrasound screening and surveillance exams from 4830 subjects performed between 2007-2017, pre-dating ultrasound LI-RADS recommendations, were assessed. Using more recent reports from May 2017-June 2018, which contained ultrasound LI-RADS specifications (1744 reports), a scalable ensemble machine learning approach was utilized to create a model that can infer ultrasound LI-RADS categories from neural word embedding analysis of the report body text. The model assigned ultrasound LI-RADS categories to the older, free-text reports (12,116 reports). Subjects who underwent serial surveillance exams were identified, and the labeled dataset was assessed for changes in LI-RADS categories over time.

RESULTS

2270 subjects had at least 2 exams. Subjects underwent an average of 5 exams, with mean screening interval of 13 months; mean follow-up duration was 43 months. When applied to the free-text reports, our model scored an average of 0.74 precision, 0.64 recall, and 0.66 F1-score, based on a validation set of 215 reports retrospectively categorized by 2 readers. According to the model's predictions, 1909 (84%) subjects remained in the same LI-RADS category over time: 1875 of these subjects remained in US-1 category, while 26 persisted as US-2; 2 patients had 2 exams each, which were both US-3. 205 (9%) progressed from US-1 to US-2. 95 (4%) alternated between US-1 and US-2. 61 (3%) subjects progressed to US-3 category during surveillance. Of these, 19 subsequently returned to US-1. In the remaining 42 subjects, the last reported ultrasound category was US-3.

CONCLUSION

Machine learning enables large-scale retrospective longitudinal evaluation of relatively recent ACR Ultrasound LI-RADS guidelines. Based on our model's predictions, 3% of patients in our cohort developed suspicious lesions to warrant further work-up.

CLINICAL RELEVANCE/APPLICATION

Our experience is the first large-scale assessment of ACR Ultrasound LI-RADS categories with longitudinal outcomes. Although retrospective, our long-term longitudinal data will be helpful in validating and improving current ACR Ultrasound LI-RADS recommendations, as well as in assessing clinical outcomes of HCC surveillance programs.

luoyanji163@163.com

PURPOSE

To evaluate the efficacy of deep convolutional neural network (DCNN) for the pathological classification of pancreatic neuroendocrine neoplasms (P-NENs) on contrast agent-enhanced computed tomography.

METHOD AND MATERIALS

One hundred and three patients (poor-differentiated [G3], n=19; well-differentiated [G1+G2], n=84) preoperatively investigated by multi spiral computed tomography (MSCT) and subsequently with histopathological proven P-NENs were enrolled. The 103 datasets

were normalized and augmented by multiple preprocessing techniques (rotated, contrast enhanced and noise-added images), and were split into training (81.6%), validation (5.8%), and test set (12.6%) with 8-fold cross validation. The DCNN with the residual learning framework (ResNet), was used to classify the images as having manifestations of poor- or well-differentiated P-NENs. The DCNN was composed of fifty convolutional, one maxpooling, one global average pooling and two fully connected layers. Training and testing were performed eight times. Accuracy, sensitivity, and specificity for categorizing poor- and well-differentiated P-NENs with DCNN model and the area under the receiver operating characteristic curve for poor- versus well-differentiated P-NENs were calculated.

RESULTS

The accuracy, sensitivity, and specificity of classifying poor- and well-differentiated P-NENs were 80.6%, 79.0%, and 81.0%, respectively. The area under the receiver operating characteristic curve for differentiating histopathological grading of P-NENs was 0.79.

CONCLUSION

Deep learning with DCNN showed high diagnostic performance in differentiating histopathological classification of P-NENs at dynamic CT images.

CLINICAL RELEVANCE/APPLICATION

The proposed framework could assist the radiologists in differentiating histopathological grading of P-NENs from contrast agent-enhanced CT images and provide prognostic information with regard to patients' outcome.

SSA09-09 Hepatic Steatosis Classification Using Deep Learning with Ultrasonic Radio-Frequency Data

PURPOSE

To develop a deep learning framework that uses radio-frequency (RF) ultrasound data for settings-independent information extraction, and assess its accuracy for classifying hepatic steatosis in adults with known/suspected nonalcoholic fatty liver disease (NAFLD).

METHOD AND MATERIALS

This was an IRB-approved, HIPPA-compliant prospective study of adults with known/suspected NAFLD. Ultrasound liver images (right lobe) and the underlying raw RF data were acquired intercostally by 2 sonographers using 4C1 and 6C1HD transducers from Siemens S3000. System settings were adjusted for each participant. Twenty liver images for each transducer were acquired for each participant. Gated RF lines from a fixed region of interest were preprocessed and used to train a deep convolutional neural network (CNN) for hepatic steatosis classification, with histology as the reference standard. No effort was made to correct for instrumentation settings. Five-fold cross validation was used for training and test. The model outputs from individual RF lines of all images were aggregated to yield a classification for a patient. As a comparison, B-mode images were graded by 8 radiologists based on their overall impression of hepatic steatosis.

RESULTS

Forty patients (sex: 16M, 24F; age: 55.5±12.3 yo; BMI: 30.2±5.4 kg/m2) were included, of which 22 had no/mild steatosis (grade 0: N=2; grade 1: N=20) and 18 had moderate/severe steatosis (grade 2: N=12; grade 3: N=6). The CNN achieved 80±5% cross-validated accuracy (72±9% sensitivity, 86±4% specificity) for identifying patients with grade 2 or 3 steatosis. By comparison, radiologists' overall impression (grade 2 or 3) for the 6C1HD transducer achieved 68% accuracy (83% sensitivity, 57% specificity) and the overall impression for the 4C1 transducer achieved 72% accuracy (77% sensitivity, 68% specificity) for the same classification.

CONCLUSION

A CNN can automatically classify human patients as having or not having moderate/severe steatosis based on RF lines acquired during liver ultrasounds using variable instrumentation settings. Preliminary findings suggest the CNN may outperform specificity of expert radiologists.

CLINICAL RELEVANCE/APPLICATION

Deep learning using the RF lines acquired during liver ultrasounds could assist radiologists in automatic hepatic steatosis classification.

PURPOSE

To compare performances of computed high b-value Diffusion Weighted Images (cDWI) derived from low b-value DWI and acquired high b-value DWI (aDWI), in image quality overall and prostate cancer (PCa) detection rate

METHOD AND MATERIALS

A total of 124 men with suspected PCa underwent diagnosis multi-parametric prostate MRI on a 3.0T MR system (SIGNATM Architect, GE healthcare) using a 32-channel phased-array torso coil. MRI protocol included 3DT2w, high resolution Fov Optimized and Constrained Undistorted Single-Shot (FOCUSTM) DWI with b-values of 100, 400, 800 and 2000 s/mm² and dynamic contrast enhanced images. cDWIs were derived from the three lower b-value DWI using a mono-exponential diffusion decay. MRI images were prospectively analyzed by one expert radiologist who provided the PI-RADS score and retrospectively by five observers (4 radiologists and 1 technician) who independently rated cDWIs (2000 and 2500 s/mm2) and aDWI (2000 s/mm2) on a 5-point scale regarding subjective image quality features (distortion, ghosting, suppression of benign prostate, anatomic clarity, rectal preparation). The 4 radiologists assessed tumor detection, conspicuity and contrast ratio with both sequences. SNR was measured in detected tumor and geometric distortion was analyzed on T2W and DWIs (diameter of the prostate from the left to the right and from anterior to posterior)

RESULTS

cDWI demonstrated higher rating for image quality ($p < 0.001$). Prostate volume >50cc and rectal preparation significantly improved image quality for all DWIs with decrease distortion ($p < 0.015$). In patients with biopsy (n=63), no significant differences were found for tumor detection rate, however cDWI improved SNR and lesion conspicuity ($p < 0.001$)

CONCLUSION

Using cDWI can provide a substantial reduction in acquisition time while improving image quality. Overall quality of diffusion weighted imaging is dependent of an adequate rectal preparation

CLINICAL RELEVANCE/APPLICATION

This post-processing technique may in practice improve visual conspicuity of tumors while maintaining high quality images, without requiring any increase in exam time

SSA10-02 Accurate Localization and Grading of Prostate Cancer with Diffusion Histology Imaging

PURPOSE

Prostate cancer (PCa) is the leading malignancy and second most common cause of death for American man. Multiparametric MRI has been employed to aid PCa diagnosis despites its significant false positive rate. The misdiagnoses are most likely caused by confounding prostatitis and/or benign prostatic hyperplasia (BPH). Non-invasive PCa grading methods has yet been developed for clinical applications. A novel diffusion histology imaging (DHI) has been developed and applied to accurately detect and grade prostate cancer.

METHOD AND MATERIALS

In vivo (262 patients) and ex vivo DHI (67 prostatectomy specimens from 22 patients) was performed. Logistic regression was used to distinguish among different tissue types. Support vector machine (SVM) algorithm was employed to construct predictive models for PCa grading.

RESULTS

Prostate diffusion-weighted MRI signals were modeled as a linear combination of an anisotropic diffusion tensor and a spectrum of isotropic diffusion tensors. Inflammatory cells, cancer cells, stromal cells and luminal structures in prostate can be detected, distinguished, and quantified as DHI-derived anisotropic and isotropic diffusion signatures. A 3D-rendered prostate from DHI was obtained from a 58-year old patient (Fig 1A). Suspicious peripheral zone PCa (pink), Transition zone BPH (gold), and peripheral zone inflammation (blue-green) was identified. In prostatectomy specimens and living subjects, DHI exhibited great sensitivity and specificity in distinguishing PCa from benign peripheral zone prostate tissues (AUC 0.955 ex vivo; AUC 1 in vivo), benign central gland (AUC 0.955 in vivo), stromal BPH (AUC 0.965 ex vivo) and BPH (AUC 0.920 ex vivo). DHI predictive model presented high overall prediction accuracy on both Gleason scores (86.4% ex vivo and 88.6% in vivo), and NCCN risk categorization (87.9% in vivo), respectively (Fig. 1B). DHI showed much better prostatic tissue classification and tumor grades prediction than ADC did (Fig. 1B).

CONCLUSION

DHI assesses various intra-gland structures of prostate, accurately localizing and grading PCa.

CLINICAL RELEVANCE/APPLICATION

Results suggest that DHI may potentially localize and grade PCa. If validated, DHI could be used to detect and grade PCa either guiding or even replacing needle biopsy. It can be used in PCa treatment stratification and monitoring, and active surveillance.

SSA10-03 Comparison of Apparent Diffusion Coefficient (ADC) Ratio to Conventional Calculated High B Value ADC for Discrimination of Gleason 3+3 and >= 3+4 Prostate Cancer in 224 Patients with 3T MRI with Whole Mount Histopathology Correlation

PURPOSE

To determine the performance of 3T MRI apparent diffusion coefficient (ADC) ratio with coventional high B value ADC for detection of high Gleason Score (GS) prostate cancer (PCa) using whole-mount histopathology (WMHP) as a reference.

METHOD AND MATERIALS

In this HIPAA-compliant, IRB-approved study, the cohort included 224 men with 249 unilateral PCa lesions with both 3T mpMRI and WMHP before and after robotic prostatectomy from NOV 2009 to NOV 2017. All studies were peformed on 3T scanners and ADC maps were derived from four b value combinations (0, 50, 500, 800) and calculated b= 1200. On an independent workstation, regions of interest (ROIs) were placed on individual WMHP verified lesions to calculate mean high b value ADC (ADC tumor_mean), lowest mean high b value ADC subregion within each PCa lesion (ADC tumor_min) and within uninvolved non tumor containing regions of the same zone to calculate background ADC (ADC benign) and the ADC ratio (ADC ratio (ADC tumor_mean or ADC tumor_min) divided by ADC benign)). The performance of individual ADC measurements in discriminating low GS (3+3) from high GS (>=3+4) PCa on WMHP was assessed using the area under the receiver operating characteristic (ROC) and area under curve (AUC) and using Spearman's rho coefficient.

RESULTS

The mean ADC was 1.573, 1.014 and 0.921× 10(-3)mm2/sec for normal (ADC benign), mean PCa lesion (ADC tumor_mean) and lowest ADC PCa subregion (ADC tumor_min), respectively. The association between ADC measurements and GS showed a significant negative correlation (P=0.001) with Spearman's rho for ADC_tumor_mean (-0.268), ADC tumor_min (-0.267) and ADC ratio (-0.366). ADC ratio had the best overall correlation with GS>= 3+4 compared with other ADC measurements. On ROC analysis, the AUCs were 0.703, 0.709 and 0.781 for ADC tumor_mean, ADC tumor_min and ADC ratio respectively for discriminating GS 3+3 from >= 3+4 PCa lesions on WMHP.

CONCLUSION

Compared with mean and minimal tumor ADC measurements, ADC ratio had the best AUC for discrimination of GS >= 3+4 from GS=3+3 PCa on 3T MRI with WMHP correlation.

CLINICAL RELEVANCE/APPLICATION

The ADC ratio as an intrapatient-normalized diagnostic tool may provide a more robust predictor for detection of GS>=3+4 compared to GS=3+3 lesions compared with tumor ADC alone.

SSA10-04 3T MRI Restriction Spectrum Imaging versus ADC in Determining and Grading Prostate Cancer in Correlation to High Gleason score and Suspicious PI-RADS v2 Scores Using Whole Mount Histopathology

Sunday, Nov. 25 11:15AM - 11:25AM Room: N229

PURPOSE

To compare restriction spectrum imaging (RSI), a multidirectional high b value technique with -conventional apparent diffusion coefficient (ADC) for detection of aggressive prostate cancer (PCa) (Gleason score (GS) > 3+4) & high suspicion Prostate Imaging Reporting and Data System version2 score (PI-RADSv2) (4&5) using whole mount histopathology (WMHP) as the gold standard.

METHOD AND MATERIALS

In this IRB approved, HIPAA compliant study, the study cohort included 77 men with both 3T- multiparametric MRI (mpMRI) & WMHP. RSI was processed from 32 direction high b value sequences & distortion was corrected using alternating phase-encode. A genitourinary (GU) pathologist marked all WMHP PCa lesions individually then a GU radiologist calculated the corresponding ROIs on RSI and ADC map by placing the ROI on PCa target & control adjacent tumor free peripheral zone (PZ) matched to WMHP. Paired Wilcoxon sign rank test was used to determine case and control correlations. Bootstrap methods was performed to determine differences between RSI & ADC in tumor grading. 2 sided p-value < 0.05 was considered significant by using SAS version 9.4.

RESULTS

In 77 men with 235 ROIs (158 PCa & 77 control) the PCa GS & PIRADS v2 scores were: 75.2% primary GS 3 & 24.8% primary GS 4. PIRADS v2 scores were 3 (16.5 %) and 4 & 5 (83.5 %). Mean RSI z score and mean ADC values in PCa & normal controls were 3.4 (-1.7 -13.6) & -0.72(-1.8 - 4.8) respectively & 1022.6 (453-1961) & 1429.3(1042-2176) respectively. The mean PCa values correlated to the control values for both RSI z-score & ADC (p<0.0001). There was positive correlation between RSI z-score & GS in all groups (3+3, 3+ 4 & >=4+3), significant between (GS 3+3 & GS >=4+3 (p=0.0003, r=0.29)) and also in all PIRADSv2 scores, significant between 3&5(p=0.0001, r=0.45)). The ADC value in PCa was inversely significant in all GS (p<0.0001, r= -0.46). RSI outperformed ADC in determining the PCa compared to control PZ regardless of the Gleason or PIRADSv2 score (AUC 0.95 vs 0.82 (p<0.0001)).

CONCLUSION

RSI is positively correlated with aggressive PCa and it outperformed ADC in determining PCa from non-cancerous regions. It may have a complementary role in predicting cancer scoring.

CLINICAL RELEVANCE/APPLICATION

RSI can be used as a complementary imaging in predicting Prostate cancer aggressivness

SSA10-05 Improving Workup of MRI-Detected PI-RADS 4&5 Lesions by Using Quantitative ADC Measurements to Obviate Unnecessary MRI Guided Biopsies

PURPOSE

To assess whether quantitative ADC measurements derived from Diffusion-Weighted Imaging (DWI) may obviate unnecessary biopsies in MRI-detected PI-RADS 4 & 5 lesions.

METHOD AND MATERIALS

This IRB-approved, retrospective study investigated 101 PI-RADS 4 & 5 prostate lesions (52 malignant, 49 benign) verified by in bore MRI-guided biopsy in 101 men (mean age, 62.8y). Two experienced uroradiologists independently and repeatedly measured minimum, mean, and maximum Apparent Diffusion Coefficient (ADC) from diffusion-weighted imaging (DWI) measurements (TR/TE 3300/60ms; GRAPPA 2, spectrally adiabatic inversion recovery [SPAIR] fat suppression; b-values of 0, 100, 400, and 800sec/mm2; six diffusion directions, bipolar diffusion sampling, acquisition time, 4:34min, 20 slices at 3.6 mm; matrix 160) by placing a two-dimensional region-of-interest around the lesions which were subsequently subjected to targeted MRI-guided biopsy. Readers were blinded to clinical information but localized the lesions based on the documented needle position during biopsy. Receiver operating characteristic (ROC) statistics were used to analyze diagnostic performance, and reproducibility statistics were calculated.

RESULTS

Minimum ADC values showed the best diagnostic performance (overall AUC R1: 0.801; R2: 0.796 peripheral zone AUC R1:0.814, R2: 0.805; transitional zone AUC R1:0.786, R2:0.779) and the tightest limits of interreader agreement (-8.6 to 9.9%). Thresholds to rule-in and rule-out any prostate cancer (PCa) were identified. Applying these 32,7% (16/49) of unnecessary biopsies could have been avoided.

CONCLUSION

The application of quantitative ADC measurements in MRI-detected PI-RADS 4 & 5 lesions may be used to avoid unnecessary MRI-guided biopsies.

CLINICAL RELEVANCE/APPLICATION

In time of increasing healthcare costs, and decreasing healthcare budgtes it is important to devolop strategies to avoid unnecessary prostate biopsies in patients with MRI suspicious PI-RADS 4 and 5 lesions.

SSA10-06 Clinically Significant Prostate Cancers with an Early Enhancement Effect on Prostate Dynamic Contrast-Enhanced MRI: Association with Clinical and Histopathological Characteristics

ttamada@med.kawasaki-m.ac.jp

PURPOSE

To determine the clinical, histopathological, and imaging features of clinically significant prostate cancer (csPC) with an early enhancement effect (EEE) on dynamic contrast-enhanced MRI (DCE-MRI).

METHOD AND MATERIALS

Eighty-eight prostate cancer patients with 127 csPCs (>0.5 cc with Gleason score (GS) =6 or >5 mm in diameter with GS>6) undergoing 3-T multiparametric MRI including T2-weighted imaging (T2WI), diffusion-weighted imaging (DWI), and DCE-MRI before radical prostatectomy were included. Two radiologists independently assigned each lesion a score of 1 to 5 for T2WI and DWI, negative (none (EEE score 0) or weak (score 1)) or positive (moderate (score 2) or strong (score 3)) EEE for DCE-MRI, and overall PI-RADS assessment category according to PI-RADS v2. Mean tumor apparent diffusion coefficients (ADCs) were also measured.

RESULTS

A total of 38 lesions (29.9%) had no EEE (non-EEE group), and 89 (70.1%) had the EEE (EEE group). The tumor detection rate of csPCs using DCE-MRI was 80.7% (71/88 patients) in the patient-based analysis. In the comparison between the groups, PSA, tumor size, Gleason score (GS) grade, and frequency of tumors with GS>3+4 were significantly higher in the EEE group than in the non-EEE group (P = 0.015 to 0.046). Tumor ADCs were significantly lower in the EEE group than in the non-EEE group (P = 0.001). In addition, the T2WI score, DWI score, and PI-RADS assessment category were significantly higher in the EEE group than in the non-EEE group (P < 0.001 to = 0.001). There were no significant differences in age, PSA density, prostate volume, tumor location (peripheral zone/transition zone), frequency of tumors with GS>3+3, D'Amico risk classification, and pathological T stage (pT2/pT3) (P = 0.059 to 0.963). The EEE score was significantly higher for tumors with GS >3+4 (n=43) than for tumors with GS = 3+3 (n=31) or tumors with GS = 3+4 (n=53) (P = 0.003 and 0.022, respectively). However, there was no significant difference in the EEE score between tumors with GS = 3+3 and tumors with GS = 3+4 (P = 0.437).

CONCLUSION

These observations suggest that csPCs with the EEE tend to be larger, more aggressive, and have higher cellularity, and the EEE may be a new predictor for differentiating between low and intermediate-risk PCs vs. high-risk PCs. However, csPCs with the EEE were easy to detect on T2WI and DWI.

CLINICAL RELEVANCE/APPLICATION

The EEE on DCE-MRI may be a new predictor for risk stratification in PC.

SSA10-07 Different Methods of AIF (Arterial Input Function) Acquirement for Quantitative Analysis of Dynamic Contrast-Enhanced MRI for Prostate Cancer Detection

Sunday, Nov. 25 11:45AM - 11:55AM Room: N229

farid.ziayee@med.uni-duesseldorf.de

PURPOSE

Primary aim of this study was to analyze if quantitative DCE allows distinction of prostate cancer (PCa) and healthy tissue in peripheral and transition zone (PZ, TZ) with use of three different methods for the determination of the arterial input function (AIF). Reproducibility of quantitative perfusion analysis of DCE requires a standardized AIF acquisition.

METHOD AND MATERIALS

We analyzed multiparametric MRI of 50 consecutive patients retrospectively with three different methods of AIF determination, either by defining a region of interest in an artery (AIFm), by use of an automated algorithm (AIFa) or thirdly with a population-based AIF (AIFp). Quantitative perfusion parameters Ktrans, ve and kep in PCa, PZ and TZ for the three different AIFs were examined.

RESULTS

In all three AIF methods, Ktrans and kep were significantly higher in PCa than in TZ ($p<0.003$), whereas ve was only significant in AIFp ($p=0.002$ in AIFp, $p= 0.114$ in AIFm, $p=0.087$ in ve). Results for PCa and PZ were significant in all methods and all quantitative parameters ($p < 0.04$). Values for Ktrans demonstrated narrowest confidence interval between the 3 methods. Overlapping of results was smallest in Ktrans. Values between AIFa and AIFm were similar whereas values for AIFp deviated considerably from AIFa and AIFm. However Spearman test showed good correlation of values for Ktrans between all methods ($p>0.7$). AIFa showed a success rate of 98% in finding the artery.

CONCLUSION

Prostate cancer can be distinguished in PZ and TZ with quantitative perfusion parameters of Toft's model independently from AIF acquisition method. AIFa is a recommendable, user-independent automatic method to determine quantitative perfusion parameters allowing an objective measurement and saving interactive time for the radiologist. Ktrans appears to be a more promising quantitative parameter for PCa detection than ve and/or kep.

CLINICAL RELEVANCE/APPLICATION

As an easily reproducible, simpe and fast method automated AIF can be implented as the standard method of AIF acquisition for quantitative DCE evaluation. Ktrans can facilitate PCa detection in both, TZ and PZ.

SSA10-08 Accuracy of IMPROD Pre-Biopsy Biparametric MRI for the Detection of Prostate Cancer in Men before Their First Biopsy: Correlation with Whole Mount Prostatectomy Sections and Implication for Focal Therapy

PURPOSE

To evaluate accuracy of high quality IMPROD biparametric prostate MRI (bpMRI) for prostate cancer in men before their first biopsy who subsequently underwent prostatectomy.

METHOD AND MATERIALS

Forty-five men with elevated PSA (2.5 - 10.0 ng/ml) underwent bpMRI examination prior their first biopsy at 3 Tesla and subsequent prostatectomy within 4 months of bpMRI. bpMRI consisted of T2-weighted imaging (T2w) and three separate diffusion weighted imaging acquisitions with acquisition time under 15 minutes (IMPROD trial protocol, http://petiv.utu.fi/improd). All bpMRI were reported by one reader before biopsy and each suspicion lesion was manually delineated on axial T2w images. Following completion of the study, radiologist in conjunction with pathologist delineated cancer areas on axial T2w images using whole mount prostatectomy, following semi-automatic co-registration, as ground true. Accuracy, expressed as area under receiver operating characteristic curve (AUC), of prospectively reported manual cancer segmentations was evaluated on interpolated isotropic voxel size of 1mm3.

RESULTS

In total 55 lesions with diameter >5 mm or any Gleason grade 4 were identified in 45 men and 4, 25, 10, 7, 9 lesions belong to ISUP Groups 1 (Gleason score <=6), 2 (Gleason 3+4=7), 3 (Gleason 4+3=7), 4 (Gleason score 8), 5 (Gleason scores 9 and 10), respectively. Prostate cancer was multifocal in 27 (60%, 27/34) men with additional 26 cancer lesions with Gleason score <=6 and diameter <=5 mm. Nine men (20%, 9/45) had more than one lesion with diameter > 5 mm or any Gleason grade 4. Seven lesions (13%, 7/55) were not identified on prebiopsy bpMRI, of those 4, 1, 1, and 1 belong to ISUP Groups 1, 2, 3 and 4, respectively. AUC (95% confidence interval on lesion level) on 1 mm3 isotropic voxel size for all lesions and ISUP Groups 1, 2, 3, 4, 5 were 0.70 (0.50 - 0.89) and 0.55 (0.50 - 0.70), 0.72 (0.51 - 0.88), 0.75 (0.65 - 0.84), 0.66 (0.54 - 0.73), 0.71 (0.50 - 0.89), respectively.

CONCLUSION

High quality prebiopsy bpMRI enabled detention of 87% of lesions with diameter >5 mm or any Gleason grade 4. However, only limited accuracy on isotropic 1mm3 voxel was achieved potentially limiting focal therapy planning.

CLINICAL RELEVANCE/APPLICATION

High quality prebiopsy biparametric MRI has high accuracy on lesion level for prostate cancer with diameter >5 mm or any Gleason grade 4. However, accuracy on isotropic 1 mm3 voxel level is limited.

SSA10-09 Prostate Cancer Detection on 3T Multiparametric Magnetic Resonance Imaging: The Impact of Tumor Focality

safsharimirak@mednet.ucla.edu

PURPOSE

To analyze the performance of 3 Tesla multiparametric magnetic resonance imaging (3T mpMRI) of the prostate for detection of prostate cancer (CaP) and identify predictors of tumor detection with particular attention to the effect of tumor focality.

METHOD AND MATERIALS

Retrospective review of prospectively maintained database of patients undergoing 3T mpMRI prior to radical prostatectomy for CaP at a single institution from 2010-2018. Radiographic lesions were assigned a suspicion score according to the Prostate Imaging-Reporting and Data System version 2 and compared to whole mount prostatectomy specimens to determine per-lesion detection by 3T mpMRI. Clinical and pathologic predictors of tumor detection were identified through multivariable analysis. Clinically significant CaP was defined as Gleason score of at least 7.

RESULTS

588 patients underwent mpMRI prior to radical prostatectomy for CaP with a total of 1213 unique pathologic cancer foci (88% intermediate or high risk), of which, 541 were detected by mpMRI for an overall sensitivity of 45% (95% CI 42%, 47%). 685 unique radiographic regions of interest were identified, of which, 132 were not associated with a pathologic lesion (false positive rate: 19%, 95% CI 16%, 22%) and 12 corresponded to the same pathologic lesion as another region of interest, for a positive predictive value of 81%. Nearly 2/3 of patients had multifocal CaP. Multifocality was associated with decreased detection of the index tumor (80% vs 66% of index tumors identified in solitary vs multifocal CaP, $p<0.001$). The majority (74%) of missed solitary tumors and a significant percentage (31%) of missed multifocal tumors were clinically significant. On multivariate analysis, smaller tumor size, lower PSA density, not using an endorectal coil, lower gleason score, non-index lesion status, pathologic stage, and multifocality were associated with lower detection rates for both any cancer and clinically significant CaP.

CONCLUSION

Pre-operative mpMRI miss a significant proportion of CaP foci. Clinicopathologic factors, including tumor focality, affect the accuracy of mpMRI, which must be understood when considering focal therapies.

CLINICAL RELEVANCE/APPLICATION

An improved understanding of the factors affecting CaP detection on 3T mpMRI is necessary as this imaging modality is increasingly incorporated into screening, diagnosis, and treatment planning.

PURPOSE

Preoperative prediction of lymph node (LN) metastasis in uterine cervical cancer remains a challenge. We aimed to investigate the value of apparent diffusion coefficient (ADC) histogram analysis in predicting pelvic LN metastasis in patients with uterine cervical cancer undergoing surgery.

METHOD AND MATERIALS

Our retrospective study included 162 cervical cancer patients (mean age, 47.7 years; range, 26-81 years) who received radical abdominal hysterectomy with pelvic LN dissection. All enrolled patients underwent routine pelvic 3T-MRI including diffusion-weighted imaging. The ADC histogram for the tumor was generated using in-house software and several histogram parameters were obtained. For predicting pelvic LN metastasis, clinical parameters (age, FIGO stage, tumor antigen [TA]-4, and histologic type) and imaging parameters (tumor size, maximal and short diameter of LN, MRI T-stage, and ADC histogram parameters) were evaluated using logistic regression analysis.

RESULTS

At histopathological findings, pelvic LN metastasis occurred in 50 patients (30.9%). In patients with LN metastasis, all ADC histogram parameters were significantly different from those without LN metastasis (all $p < 0.05$), except maximum, skewness, uniformity and entropy. At receiver operating characteristic (ROC) curve analysis, the area under the ROC curve of the 97.5th ADC percentile (ADC97.5) was 0.782, which was the greatest among other imaging and clinical variables. At univariate analysis, maximal and short diameters of LN, MRI T-stage, TA-4, tumor size and ADC97.5 were significantly associated with pelvic LN metastasis. However, the ADC97.5 was the only independent predictor of pelvic LN metastasis (odd ratio, 0.995; $p < 0.001$) (Table 1).

CONCLUSION

As an imaging marker, the ADC97.5 from histogram analysis appears to be useful for the prediction of pelvic LN metastasis in patients with uterine cervical cancer undergoing surgery.

CLINICAL RELEVANCE/APPLICATION

Preoperative ADC histogram analysis may be a useful tool to predict pelvic lymph node metastasis in patients with uterine cervical cancer, which may be helpful for clinical decision-making.

SSA11-03 Differentiation of Gynecological Sarcoma From Leiomyoma: Predictive Performance Comparison Between Radiologists and Radiomic Analysis

Sunday, Nov. 25 11:05AM - 11:15AM Room: N230B

Participants

xiehuiui1030@163.com

PURPOSE

To explore qualitative MRI features associated with gynecological sarcoma (GS). To build a predictive radiomic model, compare its performance with experienced radiologists.

METHOD AND MATERIALS

78 patients (29 GSs, 49 leiomyomas) imaged with MRI prior to surgery were included in this retrospective study. One reader evaluated their clinical data and MRI reports and marked the index lesion. Two readers blindedly evaluated each index lesion for qualitative MRI features, included: (a) intratumor hemorrhage; (b) increased vascularity; (c) intratumor necrosis; (d) tumor borderline; (e) tumor shape; and (f) uterine cavity. Association were evaluated with Fisher's exact test. The MATLAB toolbox Radiomics was used for radiomic analysis. 4 non-texture features and 43 texture features were extracted. Univariate association between all features was explored using Spearman's rank correlation. Multivariate imbalanced-adjusted logistic regression model involved bootstrap resampling was used for prediction model construction. A predictive model was evaluated using a nest cross-validation scheme. The predictive performance was evaluated by area under the receiver-operating characteristic curve.

RESULTS

Patients with GSs were older than patients with leiomyomas, $p < 0.0001$. 3 MRI features (intratumor hemorrhage, indistinct borderline and uninterrupted uterine cavity) were associated with GS, $p < 0.0001$. The AUC of predictive performance based on MRI reports made by experienced radiologists was 0.793, sensitivity :58.6%, specificity: 100%, accuracy: 84.6%. 5 radiomic features differed significantly between GS and leiomyoma were: 'Energy-GLCM-S1Q2N1', 'GLN-GLSZM-S6Q1N4', 'LGZE-GLSZM-S6Q2N3', 'Solidity', and 'SRLGE-GLRLM-S6Q1N2'. $p < 0.0001$. The highest AUC was 0.91, sensitivity :82%, specificity: 84%, accuracy: 83%.

CONCLUSION

Patients' age and three MRI features were significantly correlated with GS. Radiomic model triumphed over experience radiologists on the differentiation of GS and leiomyoma.

CLINICAL RELEVANCE/APPLICATION

Although several features at MRI can raise suspicion of a uterine sarcoma, it is difficult to differentiate from benign leiomyoma and can result in inappropriate treatment and poor prognosis.

SSA11-04 Amide Proton Transfer MR Imaging of Uterine: Comparison between Malignant and Benign Lesions

PURPOSE

To evaluate the capability of amide proton transfer (APT) MR imaging for the differentiation of uterine malignant tumor from benign lesions.

METHOD AND MATERIALS

Between October 2017 and April 2018, 58 patients with suspicious uterine lesions underwent APT MR imaging on a 3T MR scanner (Ingenia, Philips Healthcare, the Netherlands). The APT values (in percentage, representing the magnetization transfer ratio asymmetry in z-spectrum) were calculated based on images acquired from 3D TSE sequence with dual RF transmits interleave labelling. The APT values were measured on 12 lesions of pathologically confirmed endometrial adenocarcinoma, 29 lesions of leiomyomas and 21 lesions of adenomyosis with typical MR manifestation, 20 regions of normal uterine myometrium. Bonferroni's multiple comparisons test was used to compare the differences among different types of uterine lesions. Receiver operating characteristic (ROC) analyses were performed to computationally determine each feasible threshold value, sensitivity and specificity were assessed.

RESULTS

The APT values of endometrial adenocarcinoma, leiomyomas, adenomyosis, and normal uterine myometrium were 2.816±0.153, 1.504±0.156, 1.798±0.083, 1.917±0.121(mean±standard error of mean), respectively. Statistical significant differences had been found between endometrial adenocarcinoma and leiomyomas ($p<0.0001$, 95%CI 0.275~1.524), endometrial adenocarcinoma and adenomyosis ($p=0.0002$, 95%CI 0.400~1.637), endometrial adenocarcinoma and normal uterine myometrium ($p=0.0012$, 95%CI 0.275~1.524). Area under the curve of ROC analysis for differentiating endometrial adenocarcinoma from leiomyomas and adenomyosis was 0.925 and 0.968, respectively. The feasible threshold values of each group were determined as 2.37 and 2.375, with sensitivity of 83.33% and 83.33%, specificity of 89.66% and 95.24%, respectively. There were no significant differences among the APT values of leiomyomas, adenomyosis and normal myometrium.

CONCLUSION

Endometrial adenocarcinoma showed significant higher APT values than that of leiomyomas, adenomyosis, and normal uterine myometrium. There were no significant differences among APT values of uterine benign lesions and normal myometrium.

CLINICAL RELEVANCE/APPLICATION

This first attempt of APT imaging study in common uterine lesions showed the feasibility of APT weighted MRI in differential diagnosis between uterine malignant and benign lesions.

SSA11-05 PET-MRI Value for Endometrial Adenocarcinoma Staging: Initial Experience

Sunday, Nov. 25 11:25AM - 11:35AM Room: N230B

mathilde.wagner@aphp.fr

PURPOSE

To assess the performance of a positron emission tomography - magnetic resonance imaging (PET-MRI) examination for endometrial adenocarcinoma staging.

METHOD AND MATERIALS

Consecutive patients with a PET-MRI examination for endometrial adenocarcinoma staging and surgery were included. One pair of radiology/nuclear medicine physicians and one resident with experience in MRI and PET analyzed the PET-MR images. The examination included images focused on the uterus (axial diffusion-weighted, axial/sagittal T2-weighted, axial/sagittal post gadolinium T1-weighted and PET images) and whole-body acquisitions (axial diffusion-weighted, axial pre and post-contrast T1-weighted and PET images). The percentage of accurate assessment of deep myometrial invasion, nodal invasion and metastases (per patient) of 5 sets of images (1=T2+diffusion images; 2=T2+diffusion+PET images; 3=T2+diffusion+post-contrast T1 images; 4=post-contrast+PET images; 5=everything) were assessed using surgical, pathological and follow-up data as gold standard.

RESULTS

Twenty-one patients (67±8 yo) with endometrial adenocarcinoma were included. Eleven patients had a myometrial invasion deeper than 50%, 5 patients had a nodal invasion, 4 patients had a proven metastasis.The mean delay between surgery and the PET-MRI examination was 12.5 days. T2 and diffusion-weighted images allowed the highest number of correct staging of the deep myometrial invasion (17/21, 81%, without any false negative case). Adding the post-contrast images or the PET images increased the number of false positive cases. The nodal invasion assessment varied between readers and sets of images, from 50 to 81% of accurate staging. The metastatic staging was correct in 86-95% of the cases.

CONCLUSION

Adding PET images to MR images does not seem to improve imaging diagnosis performance for deep myometrial invasion assessment of endometrial adenocarcinoma.

CLINICAL RELEVANCE/APPLICATION

T2 and diffusion-weighted imaging seems to be the best combination for deep myometrial invasion assessment of endometrial adenocarcinoma. The adjunction of post-contrast or PET images does not improve the accuracy.

SSA11-06 Prediction of Malignancy in Adnexal Incidentalomas Detected on Computed Tomography: A Machine-Learning Approach

Sunday, Nov. 25 11:35AM - 11:45AM Room: N230B

Participants
Celine D. Alt, MD, Duesseldorf, Germany (*Abstract Co-Author*) Nothing to Disclose
Gerald Antoch, MD, Duesseldorf, Germany (*Presenter*) Nothing to Disclose
Sophie Heueveldop, Dusseldorf, Germany (*Abstract Co-Author*) Nothing to Disclose
Simon B. Eickhoff, Dusseldorf, Germany (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To establish a machine-learning algorithm to predict indication for surgery and malignancy of adnexal incidentalomas detected on computed tomography (CT).

METHOD AND MATERIALS

The institution database was searched from January 2013 to July 2016 for women who underwent abdominal CT scans for any indication. All patients with an adnexal lesion visible on CT and histopathological verification were included retrospectively. The institutional ethics committee approved this study and granted a waiver of informed consent. 286 adnexal lesions in 230 women were included. Based on different CT features an automated random-forest classifier was developed to predict clinical decisions and outcomes. Following development, model performance was tested on a different data set by cross-validation. Decision forests were trained and evaluated for their out-of-sample performance with respect to three different aims: (i) which tumors are radiologically conspicuous (from the group of all incidentalomas); (ii) which tumors are recommended for surgery (from the group selected in (i)); (iii) which were histologically confirmed to be malignant (from the group selected in (ii)).

RESULTS

The study cohort included 69% benign, 29% malignant, and 2% benign non-ovarian or secondary metastatic lesions. Balanced accuracies for the out-of-sample predictions were (i) 96%, (ii) 87%, and (iii) 79%. Relevant features were found to be maximum diameter, homogeneous content, septa, nodules, lipid content, solid portion, liquid content, fractal anisotropy, and box-volume.

CONCLUSION

Standardized description of radiological features of adnexal lesions in combination with machine-learning algorithms allows a reliable prediction whether an individual patient will be recommended for surgery by the subsequent gynecological evaluation and even allows to predict the outcome of the histopathological result. The proposed prediction model gives radiologists a simple algorithm for decision making in adnexal incidentalomas with respect to the necessity of further evaluation.

CLINICAL RELEVANCE/APPLICATION

An accurate assessment of an adenexal incidentaloma with a correct identification of malignancy, while avoiding unnecessary intervention for benign lesions, is crucial regarding clinical management.

SSA11-07 Comparison of Signal Intensity Ratio and ADC in Characterization of Solid Adnexal Masses on Diffusion-Weighted MR Imaging

Sunday, Nov. 25 11:45AM - 11:55AM Room: N230B

mahfouzae@yahoo.com

PURPOSE

To assess the value of signal intensity ratio versus apparent diffusion coefficient (ADC) in differentiation of benign and malignant adnexal masses on diffusion-weighted images.

METHOD AND MATERIALS

Thirty five patients with pathologically-proven solid adnexal lesions (21 malignant and 14 benign) have been examined by an identical protocol of magnetic resonance (MR) imaging, including DWI with b values of 0 and 800 s/mm2 and gadolinium-enhanced MR images. Signal intensity was measured on the b0 and b800 images by operator-determined region of interest at the same location of the lesion and the signal intensity ratio (SIR b800/b0) was calculated. ADC value was measured at the same location of the lesion. Measurements were done in the part of the lesion corresponding to enhancing part of the lesion on the gadolinium-enhanced images. Statistical analysis was done by generating receiver operator characteristic (ROC) curve and calculating the area under the curve (AUC).

RESULTS

The sensitivity, specificity, positive predictive value, negative predictive value and accuracy for diagnosis of malignancy using a cut-off value of 1.385x10-3 mm2/s for ADC were 78.95%, 37.50%, 75%, 42.86% and 66.67% respectively. Using SIR b800/b0 cut-off value of 0.33 (which is the corresponding ratio for the ADC cut-off value) the sensitivity, specificity, positive predictive value, negative predictive value and accuracy for diagnosis of malignancy were 100.00%, 75.00%, 90.48 %, 100.00% and 92.59% respectively. AUC for the ROC curves have been 0.6176 for the ADC and 0.8722 for the SIR ($p < 0.02$).

CONCLUSION

The use of SIR b800/b0 has improved the accuracy of differentiation of malignant and benign adnexal masses in comparison to the use of ADC on diffusion-weighted MR images.

CLINICAL RELEVANCE/APPLICATION

In addition to other imaging features, diffusion-weighted imaging is quite useful for differentiation of benign and malignant adnexal masses. The use of manually obtained signal intensity ratio b800/b0 instead of the machine-generated ADC values increases the accuracy of this method.

SSA11-08 Adnexal Mass Staging CT with a Disease-Specific Structured Report Compared to Simple Structured Report

PURPOSE

To assess a disease-specific structured template for CT staging of ovarian malignancy compared to a simple structured report

METHOD AND MATERIALS

This is a HIPAA-compliant, IRB-approved study with waiver of informed consent. An adnexal mass-specific structured reporting CT template was developed in collaboration between gyneco-oncologists and diagnostic radiologists. The study population included 24 consecutive women who had a staging CT prior to undergoing debulking surgery for a primary ovarian malignancy. Subjective evaluation by gyneco-oncologists and objective evaluation by radiologists for the presence of 19 key imaging features were performed to assess the clarity and usefulness for procedural planning of the disease-specific structured report (dsSR) and the simple structured report (sSR). Accuracy, sensitivity, and specificity were assessed using operating room notes and pathology reports as the reference standard.

RESULTS

Fewer key features were missing from dsSR than sSR: 0.2±0.8 (range 0-2) vs. 10.2±1.7 (range 7-14), respectively ($p<0.0001$). Compared to sSR, gynecologists deemed dsSR more helpful (4.3±0.7 vs. 3.7±0.8, $p<0.0001$) and easier to understand (4.3±0.6 vs. 3.9±0.7, $p=0.0057$) (on a scale 0-5, 0 not helpful/very difficult to understand; 5 extremely helpful/very clear to understand). Gyneco-oncologists reported a higher rate of potential to modify their surgical approach based on dsSR (33-42%) compared to sSR (13-17%) ($p=0.004$).

CONCLUSION

Disease-specific structured reports were more reliable than simple structured reports in describing key imaging features essential for procedural planning. dsSR was described as more helpful and easier to understand and more likely to lead to modification of the surgical approach by gyneco-oncologists compared to sSR.

CLINICAL RELEVANCE/APPLICATION

Disease-specific structured report is more helpful than simple structured reports for planning gynecological surgery, is easier to understand, and misses fewer imaging descriptors essential for procedural planning.

SSA11-09 MRI Evaluation of Vulvar Cancer in Fresh Radical Local Excision Specimens for Cancer Localization and Prediction of the Surgical Tumor-free Margins

Sunday, Nov. 25 12:05PM - 12:15PM Room: N230B

Participants

PURPOSE

In the surgical treatement of vulvar squamous-cell carcinoma (VSCC) tumour free margins of >=8 mm are considered adequate. The purpose of this study was to investigate the feasibility of ex vivo MRI in localizing VSCC and assess the surgical tumor-free margins in fresh radical local excision (RLE) specimens to guide the surgeon during surgical resections.

METHOD AND MATERIALS

Nine patients with biopsy-proven VSCC and scheduled for RLE were prospectively included. Intact fresh specimens were scanned using a 7T preclinical MR-scanner. Whole-mount H&E-stained slides were obtained every 3 mm and correlated with ex vivo MRI. A pathologist annotated VSCC and minimal tumor-free margins (3-, 9 o'clock, basal) on the digitalized histological slides. Both an observer with knowledge of histology (the non-blinded annotation) and a radiologist blinded to histology (the blinded annotation) performed annotation of the same features on ex vivo MRI. Linear correlation and agreement (Bland-Altman analysis) of the ex vivo MRI measurements with histology were assessed. Diagnostic performance for VSCC localization and identification of margins <8 mm were expressed in PPV and NPV.

RESULTS

In 153 matched ex vivo MRI slices, the observer correctly identified 79/91 margins as <8 mm (PPV, 87%) and 110/124 margins as >=8 mm (NPV, 89%). The radiologist correctly annotated absence of VSCC in 73/81 (NPV, 90%) and presence in 65/72 (PPV, 90%) slices. Sixty-four of 90 margins were correctly identified as <8 mm (PPV, 71%) and 83/102 margins as >=8 mm (NPV, 81%). Both non-blinded and blinded annotations were linearly correlated and demonstrated good agreement with histology. Compared to the non-blinded annotation, the linear correlation between ex vivo MRI and histology was less strong and the Bland-Altman 95% limits of agreement were wider in the blinded annotation.

CONCLUSION

Accurate localization of VSCC and measurements of the surgical tumour free margins in fresh WLE specimens using ex vivo MRI is technically feasible. The high NPV and PPV for localization of VSCC and identification of margins <8 mm demonstrate clinical applicability of the technique.

CLINICAL RELEVANCE/APPLICATION

Perioperative information on the margin status of RLE specimens provided by ex vivo MRI could assist the surgeon in achieving adequate surgical margins and prevent subsequent secondary treatment.

PURPOSE

Various sonographic features of thyroid nodules have been described, and classification systems (i.e., TI-RADS) have been developed to aid radiologists in determining which suspicious nodules require fine needle aspiration (FNA). This study aims to improve our predictive ability by training convolutional neural networks (CNNs) to discriminate between pathology-confirmed benign and malignant thyroid nodules using ultrasound images.

METHOD AND MATERIALS

Our dataset consisted of 151 malignant and 500 benign thyroid nodules from 571 patients, where each nodule contributed 1 longitudinal and 1 transverse ultrasound view. Preprocessing included cropping the nodule of interest and resizing the image to 224 x 224 pixels. The data were divided into 10 training/validation/test folds following a stratified 80%/10%/10% split with no patient overlap. CNNs based on the MobileNet architecture were initialized with pretrained ImageNet weights. A fully-connected layer was first trained for 10 epochs, and the entire network was fine-tuned for 20 epochs. Data were sampled to achieve 50%/50% class balance for each epoch. Data augmentation probability, dropout probability, and learning rate were tuned via randomized search with 60 iterations. Weights with the highest area under the ROC curve (AUC) during validation were used for testing. A malignancy score is determined for each nodule by averaging the predictions for each view across 3 models.

RESULTS

Our model achieved a mean AUC of 0.863 (95% CI: 0.827, 0.898). The median malignancy scores for benign and malignant nodules were 0.162 and 0.618, respectively. With 5 strata, (0-0.2, 0.2-0.4, 0.4-0.6, 0.6-0.8, 0.8-1.0), 5.94%, 18.2%, 29.5%, 65.7%, and 81.4% of nodules in each respective stratum were malignant, compared to an overall malignancy rate of 23.2%. At a threshold of 0.10, the model reduces the number of negative FNAs by 36% while maintaining 95% sensitivity.

CONCLUSION

CNNs fine-tuned on limited data can accurately predict the malignancy potential of sonographically suspicious thyroid nodules. Larger datasets would likely further improve the performance of our classifier. External validation studies are necessary to verify the generalizability of this approach.

CLINICAL RELEVANCE/APPLICATION

CNN malignancy scores calculated from thyroid ultrasound images can be combined with a radiologist's interpretation for improved stratification of nodules to reduce the number of unnecessary FNAs.

SSA12-03 A Deep-learning Method for Fast Detection of Rib Fracture in CT Images: Effect of Computer-Aided Diagnosis to Radiologists

Sunday, Nov. 25 11:05AM - 11:15AM Room: S406B

Participants
Xiaodong LI, Linyi, China (*Presenter*) Nothing to Disclose

For information about this presentation, contact:

lxd2018rsna@163.com

CONCLUSION

2 reading modes of CAD(CR, SR) can significantly increase the sensitivities of RFD of radiologists. The reading time is shorter by CR than by SR.CR mode can be used as the first option to detect rib fracture by radiologists.

Background

To assess the effect of rib fracture computer-aided diagnosis(CAD) on diagnosis of radiologist.

Evaluation

85 trauma CTs(50 males) with follow-up review CTs were included in the retrospective study.All trauma CTs were subjected to CAD system to generate rib fracture bounding box.The procedure of the CAD system contains ribs segmentation, centerline extraction,rib fracture detection(RFD) based on deep learning algorithm(Faster RCNN),false positive removal and rib fracture localization. 2 senior(NO.1,2) and 2 junior radiologists(NO.3,4) independently evaluated the data using 3 reading modes(without CAD,CR,SR).The fracture line or bone callus growth is the criterion for determining the rib fracture.The follow-up review CTs verified the diagnosis of rib fracture and established the reference standard[1].All fractures detected by the 4 readers were compared to the reference standard. χ^2 test and rank-sum test were performed to test whether there was significant difference between sensitivities and reading times of 3 reading modes.Abbreviations:without CAD:Radiologists independently evaluated the data.CR:Radiologists apply CAD system as a concurrent reader(CR) to evaluate the data.SR:Radiologists evaluate the data as a first reader and then apply the CAD system as a second reader(SR) to review the results.

Discussion

The reference standard identified 281 rib fractures in 85 patients.The sensitivity of RFD with SR 97.2%(273/281;P<0.001) and CR 96.4%(271/281;P<0.001) were significantly higher than that of without CAD 89.7%(252/281).There was no significant sensitivity difference between CR and SR(P>0.3). Senior and junior radiologists used CAD as CR or SR and there was no significant sensitivity difference between 2 modes(P=0.067,P=0.067).Reading time was significantly shorter for CR(98s) compared to that of without CAD(148s;P<0.001) and SR(169s;P<0.001).Reading time of the 3 modes was less in the senior group than in the junior group with significant differences(P<0.001).

SSA12-04 Highly Sensitive Identification and Delineation of Hemorrhagic Stroke Lesion Using Cascaded Deep Learning Model

CONCLUSION

A cascaded deep learning model was developed to identify and delineate hemorrhagic stroke lesion, obtaining overall sensitivity accuracy for classification with 97.91% and segmentation with 83.43%, respectively.

Background

Highly accurate and timely detection of intracranial hemorrhagic stroke is a critical clinical issue for diagnosis decision and treatment in emergency room. Deep learning is a promising approach to solve delayed and missed diagnosis of stroke accident. Accordingly, we developed a cascaded deep learning model trained by a series of different CT window settings as a preprocessing step. It consists of two convolution neural networks (CNNs) for identifying bleeding or not and fully convolutional networks (FCNs) for delineating their lesions.

Evaluation

For this study, we acquired 135,000 CT images from 5,650 patients including 3,000 non-bleeding and 2,650 bleeding. In case of bleeding, five subtypes of intracranial hemorrhage (intraventricular, intraparenchymal, subarachnoid, epidural, and subdural hemorrhage) were well labeled by experts. At first, a cascaded deep learning model was trained to identity whether there is bleeding or not and 5-fold cross validation was conducted. We evaluated sensitivity accuracy by the cascaded model, enabling to review the negative case by the second CNN trained with more narrow window width (40/40 [level/width]) in case that CT image is recognized as negative by the first CNN trained with default brain window setting (50/100). It results in increasing around 1% sensitivity (97.91%) while preserving specificity (98.76%). To delineate lesion of bleeding, the FCNs was trained with 33,300 CT slices using DGX-1 system. We achieved overall precision accuracy ranging from 70% to 90% and recall accuracy ranging from 62% to 88% at different Dice coefficient threshold as true positive decision.

Discussion

In diagnostic accuracy, there is a tradeoff between sensitivity and specificity. But while preserving specificity, the cascaded deep learning model can increase sensitivity in diagnosis of hemorrhagic stroke. It has the capability to help doctors inform any suspected cases.

SSA12-05 Differentiation of Hepatic Masses in Abdominal CT Images Using Texture-Aware Convolutional Neural Networks with Texture Image Patches

hlhong@swu.ac.kr

CONCLUSION

Our method can be applied to the differentiation of various subtypes of hepatic masses including cyst and hemangioma, and early diagnosis of hepatic cancer.

Background

Differentiation of hepatic masses into benign and malignant classes in CT images is an important task for early diagnosis and surgical decision of hepatic cancer. In the cases of small masses, acquisition of intensity and texture features is difficult, making the differentiation challenging. Thus, we propose a deep convolutional neural network (CNN) classification of hepatic masses using texture image patch (TIP) generation to enhance the classification efficiency in small masses.

Evaluation

Our method was evaluated on a dataset consisting of 349 abdominal CT scans including 576 benign and 210 malignant masses. Each mass was manually segmented by the radiologist. In TIP generation, the patches representing only the internal texture of the masses were created by filling the square patch with the segmented mass regions repeatedly. These TIPs have the effect of reflecting the texture information to CNN regardless of the original size of masses. Using these TIPs, the transfer learning (TL) was performed on the ImageNet pre-trained AlexNet to classify the patches into benign or malignant classes. To improve the classification efficiency, we re-trained the random forest (RF) classifier on the deep features extracted from the last feature layer of TL-AlexNet. In experiments, our framework was trained on 390 images(b282, m108), validated on 160 images(b113, m47), and tested on 236 images(b181, m55). The proposed method achieved the accuracy of 87.7% where the comparative methods achieved the accuracies of 83.5%, 80.1%, and 85.2%, without TIP, TL, and RF, respectively.

Discussion

Our TIPs improve the learning efficiency of CNN by augmenting the texture information of small masses and allowing the CNN to focus on the texture information. The TL also plays an important role in learning important imaging features for differentiating the hepatic masses. Instead of obtaining the CNN-classified outputs, re-training the RF classifier on the deep features improves the specificity of the proposed method by enhancing the malignancy detection.

SSA12-06 GrayNet: Medical Generic Image Representations for Deep Learning System of Urinary Stone Detection

PURPOSE

The performance of deep-learning based image analysis model developed from an institution is not guaranteed to be achieved when deployed in another if the institutions use different imaging systems with varying scan acquisition and reconstruction settings. We established a pretrained model enriched with medical generic image representations extracted from GrayNet, a dataset for human anatomy recognition with 23 labels and evaluated benefits of GrayNet pretrained models for detecting urinary stones.

METHOD AND MATERIALS

GrayNet contains 322 IV contrast-enhanced whole body CT scans with 120,182 axial slices obtained by CT scanners from two manufacturers (171 from GE and 151 from Siemens). The corresponding virtual unenhanced CT images were generated with a customized transform function. All slices were annotated as 23 radiologist-established anatomical labels. We randomly selected 40 cases for validation and the remainings were used for training of a deep convolutional neural network, Inception-v3. The best model, selected based on validation loss, was reserved as a pretrained model for urinary stone detection. Patients who underwent unenhanced CT scans from two manufacturers (GE and Siemens) for suspected urolithiasis were identified and categorized according to presence (n=128) or absence (n=161) of urinary stones, and then split into train, validation, and test subsets. Inception-v3 models initialized with random, ImageNet, and GrayNet pretrained weights were trained on training datasets from a single manufacturer and both. The optimal models were evaluated on test datasets. Area under the ROC curve (AUC) was measured for evaluation metric.

RESULTS

The performance of the GrayNet model trained on the GE dataset showed higher AUC (0.893) than the ImageNet model (0.833) when tested on the Siemens dataset. Similar trend was observed when models trained on the Siemens dataset and tested on the GE dataset (0.917 from GrayNet, 0.854 from ImageNet). When trained on the combined dataset, the GrayNet model obtained higher AUC than those of ImageNet and random models.

CONCLUSION

The GrayNet pretrained weights enabled better generalization performance, compared to the models initialized with ImageNet pretrained and random weights.

CLINICAL RELEVANCE/APPLICATION

The GrayNet pretrained weights enriched with generic medical image representations can be used as a baseline for deep learning systems for a successful deployment in varying settings.

CONCLUSION

We have presented a network trained on the largest collection of chest X-ray images with visually observable radiological findings that performs at similar accuracy to networks developed with 14 NIH labels.

Background

Despite deep learning networks now becoming the de facto method of image classification, their relevance to radiologists is limited by the semantics of label used for training such networks. Recent use of image labels such as pneumonia that are not diagnosable from imaging alone have raised concerns on the utility of the networks. We develop a new classifier for chest X-ray images by training it on labels that derived from visually observable radiological findings. We form a new combined data set of 335,688 images from three sources, namely, PLCO Chest X-rays [Gohagan 2000]), Cancer Screening Trial, National Institute of Health (ChestX-ray14 dataset [Wang 2017]) and the Indiana University dataset [Demner-Fushman 2016]. The 49 original labels assigned to these

combined datasets were mapped to the corresponding visually observable findings and regrouped into 20 finding labels. For example, 'consolidation, pneumonia, infiltration, and infiltrate' were all mapped to 'alveolar opacity'. The consolidated dataset with the new labels was used to train a DenseNet121 network architecture [Huang 2016], with 512x512 size input images preprocessed with histogram equalization and intensity normalization.

Evaluation

The dataset was divided to 80% training and 20% validation. The areas under the ROC curve for the 20 findings are: Alveolar opacity: 0.81 , Hernia: 0.84, Pneumothorax: 0.86, Atelectasis: 0.87, Aortic atherosclerosis and/or Carotid artery calcification: 0.90, Bone Lesion: 0.77, Enlarged cardiac silhouette: 0.86, Enlarged Hilum: 0.75, Findings consistent with granulomatous disease: 0.76, Hyperaeration: 0.79, Increased reticular markings: 0.71, Mass and/or Nodule: 0.64, Pleural effusion: 0.92, Pleural mass and/or thickening: 0.71, Spinal degenerative changes: 0.89, Tortuous Aorta: 0.89, Vascular redistribution: 0.85, Catheter and/or Tube: 0.89, Missing plus NA: 0.82, Other: 0.69.

Discussion

Label validation particulalry in 'no finding' labels from NIH dataset is under way.

SSA12-08 Automatic Classification and Reporting of Multiple Common Thorax Diseases Using Chest Radiographs

PURPOSE

Chest radiographs are one of the most common radiological exams in daily clinical routines. Reporting thorax diseases using chest radiographs is often an entry-level task for radiologist trainees, but it remains a challenging job for learning-oriented machine intelligence. It's due to the shortage of large-scale well-annotated medical image datasets and lack of techniques that can mimic the high-level reasoning of human radiologists. In this work, we show that clinical free-text radiological reports can be utilized as a priori knowledge for tackling these two difficult problems.

METHOD AND MATERIALS

We used a hospital-scale chest radiograph dataset, which consists of 112,120 frontal-view radiographs of 30,805 patients. 14 disease labels observed in images were mined using natural language processing techniques, i.e., atelectasis, cardiomegaly, effusion, infiltrate, mass, nodule, pneumonia, pneumothorax, consolidation, edema, emphysema, fibrosis, pleural thickening, and hernia. We propose a novel text-image embedding neural network (illustrated in the attached figure) for extracting the distinctive image and text representations. Multilevel attention models are integrated into an end-to-end trainable architecture for highlighting the meaningful text words and image regions. We first apply this combined convolutional and recurrent neural network (CNN-RNN) to classify the image by using both image features and text embeddings from associated reports. Furthermore, we transform the framework into a radiograph reporting system by taking only images as input and turning RNN into a generative model.

RESULTS

The proposed framework achieves high accuracy (0.96±0.03 in AUCs) in disease classification using both images and reports on an unseen and hand-labeled dataset (OpenI, 3,643 images). When using only the images as input, the system can also produce significantly improved results (0.80±0.07 in AUCs) compared to the state-of-the-art (0.74±0.08) with a p-value=0.0005. The figure shows sample classification results with generated reports (attended words in red).

CONCLUSION

We illustrate a framework for fully-automated classification and reporting of common thorax diseases in chest radiographs and demonstrate its superior performance compared to the state-of-the-art.

CLINICAL RELEVANCE/APPLICATION

The proposed multi-purpose CADx system can be applied for automatic classification and reporting of common thoracic diseases as a second opinion.

SSA12-09 Deep-learning for Distal Radius Fracture Detection in X-Ray Imaging

Sunday, Nov. 25 12:05PM - 12:15PM Room: S406B

Participants
Maximilian Russe, MD, Freiburg, Germany (*Presenter*) Nothing to Disclose
Mathias F. Langer, MD, PhD, Freiburg, Germany (*Abstract Co-Author*) Nothing to Disclose
Elmar C. Kotter, MD, MSc, Freiburg, Germany (*Abstract Co-Author*) Editorial Advisory Board, Thieme Medical Publishers, Inc

PURPOSE

Development of a robust algorithm for fracture detection of the distal radius in x-ray imaging for the use in an emergency department.

METHOD AND MATERIALS

Anterior-posterior x-ray images of the wrist from 2013-2017 were classified for fracture or absence of fracture by a consensus

Anterior-posterior x-ray images of the wrist from 2013-2017 were classified for fracture or absence of fracture by a consensus reading from a junior and a senior radiologist. Secondary reading was performed by a certified Msk radiologist. 1900 cases were exported for the deep learning study. Data leakage was excluded using only first-time images of the patients. Images where separated into 1351 images for training and 449 for validation. Besides the validation sample for the CNN learning, a separate analysis of the final model was performed using a separate test sample, containing 50 images with and without fractures. For the development of the deep learning model an established Convulsive neuronal network (CNN), GoogLeNet was used. Due network specifications an images distortion using a smashing transformation to 256*256 pixels was needed. The data was augmented using vertical flipping and up to +/- 10° rotation. No manual segmentation or image correction was made. Deep learning was performed by using Torch on Nvidia DIGITS with a standard workplace graphic unit (Nvidia Quadro P4000). Following parameters where used: 1000 training and validation epochs. AdaGrad was used as solver type and the initial learning rate was 0.01.

RESULTS

The training of the CNN took 4.34h of processing time. Final image processing of all 100 test images took 17 seconds. An overall accuracy of the validation sample was achieved with a final value of 94.2%, the overall accuracy of the separate test sample is 90%. The per-class accuracy in the validation sample was for fractures 87.5% and for no fractures 96.4% in the test sample 86% and 94%. These values are comparable and so overfitting of the CNN can be excluded.

CONCLUSION

The created algorithm shows a good detection rate for distal radius fractures. An exclusion of fracture was performed with even a higher accuracy. These results are promising for preliminary classification of x-rays within a clinical setting.

CLINICAL RELEVANCE/APPLICATION

X-ray reading is still a relevant task for fracture detection, fracture detection algorithms can be used to reduce the work load and already could be used for prioritizing work load. Instant preliminary fracture detection can be achieved with this deep learning model and easily implemented in clinical routine.

For information about this presentation, contact:

tetsuro.sekine@gmail.com

PURPOSE

The impact of MR-based attenuation correction on PET quantitation accuracy is an ongoing cause of concern for advanced brain research with PET/MR. The purpose of this study was to evaluate a new, template-enhanced zero-echo-time (ZTE) attenuation correction method for PET/MR scanners.

METHOD AND MATERIALS

30 subjects underwent a clinically-indicated 18F-FDG-PET/CT, followed by PET/MR on a GE SIGNA PET/MR. For each patient, a 42-second ZTE sequence was used to generate two attenuation maps: one with the standard ZTE segmentation-based method; and another with a modification of the method, wherein pre-registered anatomical templates and CT data were used to enhance the segmentation. CT data, was used as gold standard. Reconstructed PET images were qualified visually and quantified in 68 volumes-of-interest using a standardized brain atlas.

RESULTS

Attenuation maps were successfully generated in all cases, without manual intervention or parameter tuning. The PET bias with template-enhanced ZTE attenuation correction was measured to be -0.9% ± 0.9%, compared with -1.4% ± 1.1% with regular ZTE attenuation correction. In terms of absolute bias, the new method yielded 1.1% ± 0.7%, compared with 1.6% ± 0.9% with regular ZTE. Statistically significant bias reduction was obtained in the frontal region (from -2.0% to -1.0%), temporal (from -1.2% to -0.2%), parietal (from -1.9% to -1.1%), occipital (from -2.0% to -1.1%) and insula (from -1.4% to -1.1%).

CONCLUSION

These results indicate that the co-registration of pre-recorded anatomical templates to ZTE data is feasible in clinical practice and can be effectively used to improve the performance of segmentation-based attenuation correction.

CLINICAL RELEVANCE/APPLICATION

The accuracy of PET/MR attenuation correction based on zero echo time (ZTE) data can be increased with the incorporation of registered anatomical priors in the segmentation procedure.

SSA13-02 Advantages of 325ps Time-of-Flight Digital Photon Counting PET/CT in Low Dose Brain PET Performance for Assessing Breast Cancer Metastasis

Sunday, Nov. 25 10:55AM - 11:05AM Room: S504CD

Participants
Jun Zhang, PhD, Columbus, OH (*Presenter*) Nothing to Disclose
Katherine Binzel, PhD, Columbus, OH (*Abstract Co-Author*) Nothing to Disclose
Michelle I. Knopp, Columbus, OH (*Abstract Co-Author*) Nothing to Disclose
Maryam Lustberg, Columbus, OH (*Abstract Co-Author*) Nothing to Disclose
Michael V. Knopp, MD, PhD, Columbus, OH (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the feasibility and advantages of 325ps time-of-flight (TOF) digital photon counting (DPC) PET in low dose FDG brain PET performance in patients with breast cancer.

METHOD AND MATERIALS

18 low dose (3.1±0.2mCi) brain FDG-PET scans from 0-75min of 9 patients (BMI=33±6) were performed on a 325ps DPC PET/CT (Philips Vereos) to assess neurometabolic changes for breast cancer before and after chemotherapy (interval=77±10 days). 5 groups of PET reconstructions (10, 5, 2, 1 and 0.5 min) centered at 65min p.i. were performed in 3D-OSEM (2mm-isotropic) w (TOF) and w/o (nTOF). All data were co-registered and normalized based on a 43 normal FDG brain database with 90 neuro-anatomic regions created using MIMSoftware and Brain Atlas Mapping (1,620 regions total). SUV and Z-Score were calculated. NEMA phantom (6 spheres with contrast ratio of 4, 0.5-10min) and 3D-Hoffman phantom (0.5-10min, 0.6-2mCi FDG) were scanned.

RESULTS

NEMA TOF PET revealed 1.0-0.7 recovery coefficients for 6 spheres 37-10mm, with an average of 0%, 0%, 6%, 14%, 30% and 46% higher SUVmax than nTOF's, across all PET (10-0.5min). Visually, Hoffman phantom and patient data consistently revealed more robust image quality with improved details and better contrast on TOF than nTOF. No brain tumors were identified on patients. Quantitatively, an average SUVmean difference (1±3%, 1±3%, 0±2%, 2±4% and 2±5%, TOF vs nTOF) was obtained for PET 10-0.5min. Significant differences in region-based therapy response ($p<0.05$) were found between TOF and nTOF for PET <=2min. Robust Z-Scores (<=10% variance) were found on TOF PET when reducing from 10 to 1min. TOF PET demonstrated better adaptability than nTOF to scan time and dose reduction in image quality and quantification (details given at RSNA).

CONCLUSION

Compared to current standard of care FDG brain PET (10-13mCi, 10min), this low dose (3mCi) brain PET study with scan time reduction (10-0.5min) demonstrated advantages of the solid state 325ps DPC PET technology. The new technology advances neuro PET with more precise imaging of the brain enabled by the excellent TOF capability.

CLINICAL RELEVANCE/APPLICATION

Time-of-flight improvement (325ps) enabled by the new generation solid state DPC PET/CT has advantages in improving robustness of brain neuro PET acquisitions even under low dose and short scan time.

SSA13-03 The Association Between Perihematomal Edema and Iron Deposition Using Diffusion Tensor Imaging and T2* Mapping after Experimental Intracerebral Hemorrhage

PURPOSE

This study aimed to explore the relationship between iron deposition and perihematomal edema after intracerebral hemorrhage (ICH) by diffusion tensor imaging (DTI) and T2* mapping.

METHOD AND MATERIALS

14 male SD rats were included in ICH group. 6 rats were included as normal controls. In ICH group, 40 μL of autologous blood was injected into the right basal ganglia to mimic spontaneous ICH. All rats underwent T2WI, DTI and T2* mapping on a 7.0 T animal MRI. The time points of scan of DTI and T2* mapping were days 1, 3, and 7. We used T2WI images scanned at 3-6 h after ICH to measure the initial hematoma. Abnormal mean diffusivity (MD) value and volume were calculated by MD maps. T2* value and abnormal T2 * value volume were measured using T2* mapping maps.

RESULTS

In ICH group, the initial hematoma was 19.14 ± 8.151 μL. The T2* values were 21.23 ± 2.40 ms, 20.62 ± 2.96 ms, and 17.97 ± 2.54 ms at 1d, 3d and 7d after ICH in the ipsilateral side and were 32.47 ± 2.11 ms, 32.51 ± 2.74 ms, and 32.43 ± 3.71 ms in the contralateral side. In normal control group, T2* value was 32.73 ± 2.55 ms in the ipsilateral side and was 33.07 ± 2.16 ms in the contralateral side. The T2* value in the ipsilateral side in ICH group were significant lower than normal control group at 1d, 3d and 7d after ICH, respectively (all $P < 0.001$). There were no significant differences in T2* value between the contralateral side and normal group (all $P > 0.05$). The volumes of abnormal T2* value were 30.93 ± 18.55 μL, 25.30 ± 9.27 μL, and 31.50 ± 10.58 μL and the volumes of abnormal MD were 48.86 ± 31.51 μL, 64.30 ± 64.72 μL, and 30.63 ± 24.99 μL at 1d, 3d and 7d after ICH. A positive correlation was observed between abnormal T2* volume and abnormal MD volume at 1d after ICH ($r = 0.92$, $P < 0.001$).

CONCLUSION

There was a positive correlation between abnormal T2* volume and abnormal MD volume at 1d after ICH. DTI and T2* mapping has the potential to explore the relationship between perihematomal edema and iron overload after ICH.

CLINICAL RELEVANCE/APPLICATION

DTI and T2* mapping can not only diagnose the edema and iron overload in hematoma and perihematomal area after ICH, but also explore the relationship between iron deposition and perihematomal edema.

SSA13-04 Imaging Type-Three Diabetes in an Alzheimer's Disease Animal Model: A Preliminary Mouse Study

Sunday, Nov. 25 11:15AM - 11:25AM Room: S504CD

Participants
Val J. Lowe, MD, Rochester, MN (*Abstract Co-Author*) Research Grant, General Electric Company; Research Grant, Siemens AG; Research Grant, Eli Lilly and Company; Advisory Board, Merck & Co, Inc
Tyler J. Bruinsma, BA, Rochester, MN (*Presenter*) Nothing to Disclose

vlowe@mayo.edu

PURPOSE

Investigating the brain distribution of iodine-125 labeled insulin (125I-Insulin) by dynamic single photon emission computed tomography/computed tomography (SPECT/CT) in mice with and without metabolic syndrome and/or Alzheimer's disease (AD).

METHOD AND MATERIALS

Six-month-old APP/PS1 mice (n=6) and wild type (WT) littermates (n=6) were split into two groups. Half were fed a high fat diet (HFD) while half were fed a regular chow diet (RCD) for four months. Insulin tolerance tests were performed at 1 and 4 months after feeding began. A bolus injection of 125I-Insulin was administered via the femoral vein and each mouse was imaged with SPECT/CT. Regions of interest were drawn around the brain and standard uptake values (SUV) were calculated. Following the imaging protocol, mice were perfused with PBS and individual brain regions and peripheral organs were harvested and assayed for 125I activity in a dual channel gamma counter. One-way ANOVA, repeated measures ANOVA, and Student's t-test were used to assess the significance of results.

RESULTS

Blood glucose levels in HFD mice showed diminished response to insulin compared to RCD littermates ($p<0.001$). APP/PS1 mice on both HFD and RCD showed attenuated reductions in blood glucose during the insulin tolerance test ($p<0.02$). The HFD mice had significantly higher brain 125I-Insulin SUV at all time points as compared to RCD mice ($p<0.005$). In the RCD cohort, WT mice showed greater brain SUV than the APP/PS1 mice between 30-60 minutes ($p<0.005$). Post-perfusion gamma counts revealed significantly lower retention of 125I-insulin in the eyes and brains of HFD mice as compared to RCD mice ($p<0.05$).

CONCLUSION

Although, HFD causes peripheral insulin resistance in both WT and APP/PS1 mice, the imaging showed an unexpected increase in these mice. In contrast, lower insulin retention post-mortem was seen in both WT and APP/S1 mice on HFD. Greater peripheral insulin resistance and lower brain insulin retention in APP/PS1 mice compared to WT mice suggests the impairment of insulin delivery that triggers 'type-three diabetes' in the AD brain. Further work is necessary to better understand the brain kinetics of insulin.

CLINICAL RELEVANCE/APPLICATION

Insulin molecular imaging is a promising new frontier for elucidating the underlying connection between AD and insulin resistance.

SSA13-05 Imaging Amyloid Plaques Without Contrast Agent

Sunday, Nov. 25 11:25AM - 11:35AM Room: S504CD

Participants
Eshan Dahal, Silver Spring, MD (*Abstract Co-Author*) Nothing to Disclose
Bahaa Ghammraoui, Silver Spring, MD (*Abstract Co-Author*) Nothing to Disclose
Aldo Badano, PhD, Silver Spring, MD (*Presenter*) Nothing to Disclose

PURPOSE

PET is clinically used to quantify brain amyloid load in vivo in Alzheimer's disease (AD) patients, but requires the use of amyloid-specific radiotracer and provides no information on plaque structure. We study small-angle x-ray scattering (SAXS) imaging for structural characterization of amyloid plaques in human brains and quantification of the amyloid load without contrast agent. Experimental SAXS images of an amyloid plaque model and Monte Carlo simulations of diagnostic energy x-ray transport in a human head digital model are reported to determine SAXS system design choices for amyloid imaging.

METHOD AND MATERIALS

SAXS measurements were performed using a point collimation mode and monochromatic x-ray beam. Simulations of a SAXS-CT geometry in a voxelized human head (MIDA model) were performed using a publicly available GPU-accelerated Monte Carlo radiation transport tool. SAXS-CT images of the brain with varying amyloid load at relevant q angles were reconstructed using filtered back projection (FBP).

RESULTS

SAXS measurements of amyloid fibrils pellet show strong scattering with distinct peaks around 6.4 and 13.4 nm-1 due to the ß-sheet fibrillar structure. SAXS is capable of detect amyloid plaques without any contrast agent based on their scattering signature. SAXS-CT simulations performed on a human head digital model with inserted amyloid plaques show feasible detection of plaques as small as 2 mm. More realistic SAXS-CT simulation requires measured cross-section models of amyloid in the brain with different mass fraction of plaques. This allows optimizing the SAXS imaging system to detect micrometer-sized amyloids near 6.4 nm-1.

CONCLUSION

Our results showcase the potential of SAXS imaging method to image amyloid plaques in the human brain and to quantify amyloid load without using contrast agent.

CLINICAL RELEVANCE/APPLICATION

SAXS may surpass the amyloid imaging performance of PET if it can detect and image amyloids in the early stage of plaques

deposition in AD patients with an effective radiation dose of 10 mSv or lower.

SSA13-06 Features of Corticospinal Tract Using Diffusion Tensor Imaging After Experimental Intracerebral Hemorrhage

PURPOSE

To dynamically evaluate the effect of hematoma on corticospinal tract (CST) after intracerebral hemorrhage (ICH) by diffusion tensor imaging (DTI).

METHOD AND MATERIALS

29 male SD rats were injected with 40uL of autologous blood from tail in the right basal ganglia. DTI sequence was scanned on 7.0T MRI at day 1 (D1), day 3 (D3), day 7 (D7), day 14 (D14), day 21 (D21) and day 28 (D28) after ICH. Sham and normal controls underwent the same scan. The initial hematoma volume was obtained from T2WI images (3-6h after ICH). Mean diffusivity (MD), axial diffusivity (AD), radial diffusivity (RD) and fractional anisotropy (FA) were obtained from DTI maps. The regions of interest included cerebral peduncle (CP) and pyramidal tract (PY). Modified neurological severity score (mNSS) was used to evaluate the neurological function of rats.

RESULTS

FA values of ipsilateral CP in ICH group were significant lower than in sham group at D1, D3, D7, D14 and D21 (all $p < 0.05$). FA values of ipsilateral CP in ICH group at D3, D7 were significant lower than normal controls (both $p < 0.01$). MD of ipsilateral CP in ICH group at D1 was significant higher than sham group and at D28 was significantly lower than sham group (both $p < 0.05$). AD of ipsilateral CP at D7 and D28 in ICH group was significantly lower than in normal group (both $p < 0.05$). RD of ipsilateral CP in ICH group was higher than sham group at D1 and D3 and lower at D28 (all $p < 0.05$). No significant differences were found in DTI parameters in ipsilateral and contralateral PYs between ICH group and sham group, and among different time points and normal controls (all $p > 0.05$). The scores of mNSS in ICH group were significantly greater than in sham group (all $p < 0.05$). The score of mNSS in ICH group at D1 was significantly greater than other time points (all $p < 0.05$).

CONCLUSION

DTI parameters of ipsilateral CP were abnormal, whereas no changes in DTI parameters of PY were found in ICH model induced by 40uL autologous blood. DTI has the potential to detect dynamically the effect of hematoma on CST.

CLINICAL RELEVANCE/APPLICATION

DTI reveals the changes of CST in parameters after ICH at basal ganglia.

SSA13-07 The rCBV with Contrast Leakage Correction Improves the Correlation Between MR Perfusion Weighted Imaging and Fluorine-18-Deoxyglucose Positron Emission Tomography in Patients with Brain Tumors

Sunday, Nov. 25 11:45AM - 11:55AM Room: S504CD

Participants
Xiang Liu, MD, Rochester, NY (*Presenter*) Nothing to Disclose
Wei Tian, MD,PhD, Rochester, NY (*Abstract Co-Author*) Nothing to Disclose
Henry Z. Wang, MD, PhD, Pittsford, NY (*Abstract Co-Author*) Consultant, VirtualScopics, Inc

Xiang_Liu@URMC.Rochester.edu

PURPOSE

Tumor angiogenesis and tumor metabolite are important for clinical management for patients with brain tumors. Although rCBV without contrast leakage-correction is the most widely used imaging parameter of MR dynamic susceptibility contrast perfusion weighted imaging (DSC-PWI), the rCBV with contrast leakage-correction was reported to have better accuracy in the evaluation of tumor hemodynamic abnormality. The purpose of this study is to compare the correction between these two rCBV parameters and fluorine-18-deoxyglucose (FDG) positron emission tomography (PET).

METHOD AND MATERIALS

85 paired MR DSC-PWI and FDG-PET examinations in 65 patients with brain tumors, including high grade gliomas, brain metastases and cerebral lymphomas, were enrolled in this study. The interval between MR DSC-PWI and FDG-PET examinations ranged from 0 to 13 days in 72 paired MR DSC-PWI and FDG-PET examinations, another 13 paired stable post-surgical scans were acquired within 28 days. The rCBV maps without and with contrast leakage correction were generated using FDA-approved GE BrainStat and NordicICE programs. Two neruoradiologists measured the maximal rCBV ratio and the tumor versus normal tissue count ratio (TNR) in the "hot" ROIs. The correlation between maximal rCBV ratio of rCBV without and with contrast leakage correction and TNR was evaluated with Spearman Rank correlation analysis, and the difference between these two correlations was assessed with paired t-test.

RESULTS

The mean maximal rCBV ratio of rCBV with contrast leakage correction (1.65±1.38) were higher than rCBV without contrast leakage

correction (1.02 ± 0.876, p=0.03). The rCBV with contrast leakage correction has better correlation with FDG-PET-TNR (Correlation coefficient =0.618, p<0.001) than rCBV without contrast leakage correction (Correlation coefficient =0.436, p=0.018), p<0.001.

CONCLUSION

The rCBV with contrast leakage correction shows better correlation with FDG-PET-TNR. Combing different MR-DSC-PWI and FDG-PET parameters could provide comprehensive information of tumor hemodynamic change and tumor metabolic abnormality.

CLINICAL RELEVANCE/APPLICATION

The rCBV with contrast leakage correction shows better correlation with FDG-PET-TNR. Combing different MR-DSC-PWI and FDG-PET parameters could provide comprehensive information of tumor hemodynamic change and tumor metabolic abnormality.

PURPOSE

To determine therapeutic effect of peptide functionalized NP in restraining brain tumor growth by blocking cMET Signaling

METHOD AND MATERIALS

A dendrimer-based nanoinhibitor(Den-CMBP) has been developed using MET targeted cMBP peptides conjugated on G4 dendrimer. Binding affinity of Den-CMBP and free CMBP was evaluated using Surface Plasmon Resonance(SPR) Technology. Cellular responses including cell apoptosis, viability, proliferation were evaluated by treatment with Den-CMBP at various concentrations.GBM rodent models were developed by U87-MG cells implantation. Expression of cMET and downstream signature proteins were tested in U87-MG tumor cells and U87-induced mice models by Western blotting analysis. Mice bearing GBM tumors were treated with Den-CMBP, free CMBP and PF-04217903, a small molecular MET inhibitor, respectively. In-vivo MRI was used to assess tumor volume pre and post treatment. Immunofluorescence staining was performed to evaluate MET immnuno-activity post treatment. Survival was calculated for three sub-groups.

RESULTS

Compared to the free cMBP peptide(KD = 3.964 × 10-7 M), the binding affinity of the nanoinhibitor increased three-order of multitude to 1.316 × 10-10 M due to the multivalent effect. Nanoinhibitor efficiently blocked MET signaling with remarkably reduced levels of phosphorylated MET and its downstream signaling proteins in GBM tumor models and U87MG cell culture. In vivo T2-weighted MRI showed significant tumor growth restraint post treatment of nanoinhibitor. The volumes of tumor treated with Den-cMBP1 were recorded as 0.019, 0.408, and 3.659 mm3 at 7, 15 and 21 days, which decreased 63.5%, 80.0% and 78.3% respectively compared to the control group. No obvious therapeutic effect was observed after administration of free cBMP peptide, nanoinhibitor demonstrated remarkable therapeutic responses similar to PF-04217903. Immunoblotting studies verified that the nanoinhibitor attenuated glioma growth by inhibiting MET downstream signaling. Median survival was extended to 35 days with treatment of nano inhibitors.

CONCLUSION

Overall, this work developed a dendrimer based MET targeted nanoinhibitor that effectively inhibits glioma growth by blocking MET downstream signaling, which would provide an alternative therapeutic strategy for tumor therapy.

CLINICAL RELEVANCE/APPLICATION

The multivalency of dendrimer based NPs would help to decrease dosage and side-effects as well.

SSA13-09 Dynamic Cell Tracking with Time-Lapse MRI: The Temporal Window for Detection of Inflammatory Disease

Sunday, Nov. 25 12:05PM - 12:15PM Room: S504CD

PURPOSE

While several imaging techniques apply various approaches for cell tracking, the actual dynamic process remained concealed for non-invasive imaging in deep tissue until recently. With the concept of time lapse MRI, real time tracking of individual cells has

become possible. Here, we investigate which velocity range of cell motility can be resolved and investigate time Lapse MRI to track immune cell motility in a model of multiple sclerosis.

METHOD AND MATERIALS

A time lapse MRI protocol using a T2*w gradient echo sequence with a single frame scan-time of 8min12s was developed on a 9.4T small-animal MRI. Movies were composed of images from 20 repetitions. Phantom scans were performed on Resovist-labelled monocytes. In vivo scans were performed in healthy (n=6) and experimental autoimmune encephalomyelitis (EAE, n=14) mice (C57BL/6J) injected i.v. with Resovist 24h prior to MRI. Simulations were performed with a synthetic phantom reproducing the observed contrast of one labelled cell. Motion was simulated by composing synthetic k space data with different fractions obtained from different positions of the synthetic cell.

RESULTS

Phantom and in vivo scans confirmed that labelled immune cells could be tracked in the brain. Simulations showed that moving cells up to velocities of 1µm/s were detectable. In EAE mice significantly reduced numbers of in vivo labelled immune cells were observed as compared to naïve mice (253±29, n=6 vs 31±6, n=14). In EAE mice significant differences were observed before (45±9, n=6) versus after onset (21±4, n=8) of symptoms.

CONCLUSION

Time lapse MRI proofed sensitive enough to detect "patrolling" immune cells along the endothelium. With the start of the leucocyte-adhesion cascade in inflammation, cells start "rolling" with a higher velocity, resulting in less detected cells in EAE. Thus, time lapse MRI enables for assessing immune cell dynamics non-invasively and may serve as a tool for detection or monitoring of an inflammatory response prior to onset of clinical symptoms.

CLINICAL RELEVANCE/APPLICATION

Time lapse MRI may be a versatile tool for studying onset and type of innate immune response by non-invasive, real-time imaging of dynamic immune cells in the brain.

PURPOSE

We aimed to compare different MRI-based assessments of bone marrow adipose tissue (MAT) at different anatomic locations and its correlation with physical activity.

METHOD AND MATERIALS

As part of the population-based KORA study, largely healthy subjects underwent whole-body MR imaging including a 2-point-T1-DIXON-VIBE (2pDIXON) sequence (entire body) and a multi-echo DIXON (ME) sequence (upper abdomen). MAT was quantified in the L1 and L2 vertebrae using both sequences, in the femoral necks using the 2pDIXON. In the 2pDIXON, MAT percentage was calculated as the mean value of the fat image divided by the sum of the mean values of the fat and water image. In the ME sequence, MAT percentage was directly derived from the output images, which accounted for R2*. Physical activity was determined by standardized questionnaire.

RESULTS

A total of 385 subjects (96%) were included in the analysis (56±9.1yrs, 58% male); with an evenly distributed physical activity pattern (29% >2h/week; 31% 1h/week; 15% 1h/week (irregularly); 26% no physical activity). Based on the 2pDIXON, MAT was 52.6±10.2% in L1, 56.2±10.3% in L2, 87.4±5.9% in the right and 87.2±5.9% in the left femur neck, while in the ME sequence MAT was significantly lower (43.0±8.0% and 44.1±7.9%, for L1 and L2, all $p<0.001$; respectively). Both MAT measurements in the vertebrae were strongly correlated (r: 0.81 to 0.93), in contrast, correlation of MAT between vertebrae and femoral necks was weak (r: 0.36 to 0.46). All vertebral bone marrow fat measurements were inversely associated with high physical activity (>2h/w), but no correlation was found with the femoral necks (all $p>=0.35$). Strongest association was observed for L1, derived from the 2pDixon (ß= 3.9, $p=0.005$). This association remained significant when adjusted for age, gender and waist circumference ($p=0.005$). Also, high reproducibility, assessed in a subset of 30 subjects, was observed in the 2pDIXON measurement at L1 (ICC for inter- and intra-reader: 0.92 and 0.90).

CONCLUSION

Physical activity was negatively correlated with MAT in the L1, L2 vertebrae but not with the femoral necks. 2pDIXON depicted that correlation better than the ME sequence.

CLINICAL RELEVANCE/APPLICATION

MAT is centrally involved in many metabolic processes and may serve as a proxy for bone health/disease, e.g. osteoporosis. Its different dependence on physical activity at different body locations may contribute to a better understanding of related pathophysiology.

SSA14-02 Application of Texture Analysis in the Differential Diagnosis of Osteoblastic Metastases and Enostoses: Comparison with CT Attenuation Measurements

Sunday, Nov. 25 10:55AM - 11:05AM Room: E353C

Participants
Seong Woo Jeon, MD, Suwon, Korea, Republic Of (*Presenter*) Nothing to Disclose
Kyu-Sung Kwack, MD, PhD, Suwon, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Sunghoon Park, MD, Suwon, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

The purpose of this study was to investigate the role of CT texture in distinguishing between osteoblastic metastases from enostoses and to compare the results with CT attenuation values.

METHOD AND MATERIALS

The study group comprised 32 patients with 64 sclerotic bone lesions found at CT (41 enostoses in 24 patients and 23 metastases in 8 patients). For each lesions in spine, CT texture analysis was performed by drawing a region of interest on axial CT slices. The histogram parameters (mean, SD, kurtosis, entropy, and skewness) were acquired using a research software 'TexRAD'. The diagnostic performances of mean CT attenuation values and texture analysis for differentiating osteoblastic metastases from enostoses were evaluated.

RESULTS

Mean CT attenuation values had the best diagnostic performance with an ROC AUC (Az) of 0.953 among all parameters. Among CT texture analysis parameters to differentiate osteoblastic metastases and enostoses, the kurtosis had the highest ROC (Az = 0.787) than the entrophy (Az = 0.763) and skewness (Az = 0.691). The combination of mean attenuation and CT texture analysis parameters had poorer performance than mean CT attenuation values alone.

CONCLUSION

Using texture analysis does not improve diagnostic performance in the differentiation of osteoblastic metastases and enostoses in the spine.

CLINICAL RELEVANCE/APPLICATION

CT texture analysis may have a spectrum of potential application in lesion characterization for some tumor types. However, based on our data, we cannot recommend adding CT texture analysis to differentiate osteoblastic metastases of the spine.

SSA14-03 Differentiation of Osteomyelitis from Reactive Osteitis in the Patients with Diabetic Foot Using Multivariable Logistic Regression Analysis

Sunday, Nov. 25 11:05AM - 11:15AM Room: E353C

Participants
Yong-ho Jang, MD, Suwon, Korea, Republic Of (*Presenter*) Nothing to Disclose
Kyu-Sung Kwack, MD, PhD, Suwon, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Sunghoon Park, MD, Suwon, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To retrospectively investigate the differentiating magnetic resonance (MR) imaging findings between osteomyelitis and reactive osteitis in the patients with diabetic foot.

METHOD AND MATERIALS

From November 2015 to March 2018, 118 patients who underwent MRI of the foot for evaluation of suspected osteomyelitis were included in this study. Primary (signal intensity, distribution, and pattern on the T1-weighted images, signal intensity on the T2-weighted images, and concordance of marrow signal intensity) and secondary MR imaging signs (cortical interruption, cellulitis, ulcer, soft tissue abscess, and gangrene) were retrospectively reviewed. To identify the MR features differentiating osteomyelitis from reactive osteitis and to evaluate their differentiating accuracy, multivariate regression and receiver operating characteristic (ROC) curve analysis were performed.

RESULTS

On MRI findings, signal intensity, distribution, and pattern on the T1-weighted images, signal intensity on the T2-weighted images, concordance of marrow signal intensity, cortical interruption, ulcer, soft tissue abscess, and gangrene were significantly different between two groups ($p < 0.05$). Multivariate regression analysis showed that the bright T2 signal intensity (OR 17.7, $p < 0.001$) and deep ulcer (OR 5.6, $p = 0.009$) were major factors associated with osteomyelitis. The area under the ROC curve of predicted probabilities for the combination of these factors was 0.879.

CONCLUSION

In the patients with diabetic foot, osteomyelitis can be accurately distinguished from reactive osteitis by the bright T2 signal intensity and deep ulcer.

CLINICAL RELEVANCE/APPLICATION

Identification and application of these MR features are important to analyzing radiological imaging in the patients with the diabetic foot and can help the radiologist to differentiate osteomyelitis from reactive osteitis

SSA14-04 Predicting Osteomyelitis in Patients with Equivocal MRI Findings

alisax87@gmail.com

PURPOSE

Specificity of MRI in diagnosing osteomyelitis (OM) in the diabetic foot with ulceration is confounded by high frequency of equivocal findings (abnormal signal on T2fs/STIR sequences with normal signal on T1w sequences). We sought to determine the strongest risk factors for development of osteomyelitis in this setting.

METHOD AND MATERIALS

We analyzed MR exams of diabetic patients with pedal ulcers and suspected osteomyelitis who were indeterminate for OM based on discordant bone marrow signal (normal T1, abnormal T2fs/STIR) adjacent to the ulcer. Follow-up imaging and/or surgical results determined outcome (OM or non-OM). Ulcers were categorized based on surface area and depth (distance to bone). Patterns of marrow edema (subcortical vs medullary) were recorded. The ratio of marrow to joint fluid signal on T2fs/STIR sequences was measured. Statistical analysis was performed with a two-sample t-test and a Cox proportional hazard model.

RESULTS

60 MR exams were identified. 26 showed resolution of marrow findings (no osteomyelitis) and 34 progressed to osteomyelitis. Marrow ROI/joint fluid ratios averaged 65% (39-87%) in the OM group, and 45% (17-97%) in the non-OM group, $p < .001$. ROI ratios > 53% had a 6.5-fold increased risk of osteomyelitis, $p < .001$. Proximity to bone averaged 6mm in the OM group and 9mm in the non-OM group, $p = .02$. Ulcer size averaged 4 cm2 in the OM group versus 2.4 cm2 in the non-OM group, $p = .07$. Ulcers greater than 3cm2 had a 2-fold increase in the risk of osteomyelitis, $p = .04$.

CONCLUSION

High bone marrow/joint fluid signal ratio on T2fs/STIR images was the strongest risk factor for development of osteomyelitis, with a ratio > 53% portending an 6.5-fold increased risk of osteomyelitis. Ulcer size and depth to bone are weaker predictors for the development of osteomyelitis.

CLINICAL RELEVANCE/APPLICATION

Diabetes affects 9.3% of US citizens, 25% of which develop a foot ulcer, the most significant risk factor for amputation. A test that could accurately predict early osteomyelitis in this population would significantly reduce morbidity.

SSA14-05 Assessment of Early Treatment Response by MRI in Multiple Myeloma: Comparative Study of Whole-Body MRI and Lumbar Spinal MRI

PURPOSE

This study compared remission status at completion of chemotherapy with changes in MRI biomarkers obtained from whole-body diffusion-weighted imaging (wb-DWI) and lumbar spinal chemical shift imaging soon after induction of chemotherapy, and compared the predictive value of the MRI biomarkers for complete response (CR).

METHOD AND MATERIALS

Forty-two patients with symptomatic myeloma were examined before and after two cycles of chemotherapy using a 3-T MRI system (Ingenia; Philips Healthcare). For wb-DWI, coronal images were acquired by free-breathing single-shot echo-planar DWI with b-values of 0 and 1000. Total tumor volume (tTV) was obtained by semi-automatic segmentation of wb-DWI using a discriminant analysis method. The threshold for positive bone marrow (BM) involvement was an apparent diffusion coefficient (ADC) >0.55×10-3mm2/s according to a previous report. The mean fat fraction (FF) was calculated from the BM of the L1 to L3 vertebrae without a focal lesion using the coronal 3D 2-point mDIXON quant sequence. Coronal wb-T1 weighted, axial wb-T2 weighted, sagittal spinal STIR, and T1-weighted images were acquired. Serological data were also obtained. At the completion of chemotherapy, the patients were categorized into a CR group (n=12) or a non-CR group (n=30).

RESULTS

No significant differences in the baseline serological- and MRI-derived indices were observed between groups. At the second

examination, tTV, M protein, and ß2-microglobulin were significantly decreased and 75th percentiles of ADC and FF were significantly increased in the CR group. The general linear model demonstrated that percentage changes in FF and M protein contributed significantly to the achievement of CR (P=0.01, P=0.03, respectively). AUCs of ROC curves were 0.876 for FF and 0.843 for M protein.

CONCLUSION

Early change in the FF of lumbar BM soon after induction of chemotherapy was a significant predictor of CR. Total TV obtained by wb-DWI did not prove to be a significant predictor of CR. The sensitivity of FF in the lumbar BM for identification of CR was higher than M protein.

CLINICAL RELEVANCE/APPLICATION

Early change in the FF of lumbar BM soon after induction of chemotherapy is a predictor of CR, suggesting that lumbar spinal MRI can be used to predict remission status.

SSA14-06 MRI Radiomics in the Longitudinal Analysis of Desmoid Fibromatosis Undergoing Systemic Therapy

PURPOSE

Desmoid-type fibromatosis exhibits unique morphological changes on MRI in response to systemic therapy. We sought to quantify the longitudinal changes in appearance of treated tumors to better elucidate the relationship between morphological and textural imaging features.

METHOD AND MATERIALS

This IRB-approved retrospective study included 16 extra-abdominal lesions in 11 subjects (mean age 37 years), 6 females and 5 males. Therapeutic regimens included cytotoxic chemotherapy (n=7), tyrosine kinase inhibitor (n=2), tamoxifen (n=3), and NSAIDS (n=2). Tumors were segmented using 3D-Slicer, and features were extracted with the Radiomics extension; data included tumor shape, signal intensity (tumor: muscle enhancement ratio), and image texture. Response was classified at the lesional level by RECIST1.1 maximum diameter (Dmax) thresholds for progressive disease (>20% increase from nadir, PD), partial response (>30% decrease from baseline, PR), or otherwise stable disease (SD).

RESULTS

The 16 lesions were followed for mean of 5.1 years (range 9 months -14 yrs); this included a total of 100 distinct timepoints. Baseline mean Dmax=10 cm (range 4.2-173 cm), volume 176 cc (range 8-796 cc), and mean enhancement ratio 1.8 (range 0.9-4.0). By RECIST1.1 6 lesions remained stable, 6 lesions showed PD (median progression free survival 1.8 yrs). Only 4 lesions (25%) achieved PR (median time to PR 3.9 yrs), while 13/16 (81%) showed a drop in enhancement ratio (mean -46% from baseline). 12/16 (75%) tumors exhibited at least >20% drop from baseline (median 2.6 yrs). Dmax correlated poorly with enhancement ratio (r=0.09). A random effects GLS regression model containing shape-based, first-order, and textural features established skewness (p=0.008), minor axis length (p=0.04), and run entropy (p=0.05) as significant independent predictors of contrast enhancement ratio.

CONCLUSION

Most desmoid fibromatoses show substantial decreased enhancement after systemic treatment despite relative stability in size. Desmoid segmentation enables identification of radiomic biomarkers that reflect clinically relevant longitudinal changes in tumor phenotype.

CLINICAL RELEVANCE/APPLICATION

Consistent and durable decreases in tumor enhancement support augmenting or replacing size-based with signal-based imaging response criteria for desmoid tumors undergoing systemic therapy.

SSA14-07 Differentiating Lipomatous Masses with High-Resolution 1H MRS Metabolites: Do Benign Lipomas and Atypical Lipomatous Tumors Have a Distinct Metabolic Signature?

PURPOSE

Adipocytic tumors represent a spectrum of neoplastic disease from benign lipomas and variants, to atypical lipomatous tumors (ALTs) and liposarcomas. Some liposarcomas are suspected to arise through dedifferentiation of ALTs. The distinction of liposarcomas and premalignant ALTs can be a diagnostic challenge, as can the distinction of ALTs and lipoma variants (lipomas without pure lipid composition), with implications for surgical and clinical management. The purpose of this study is to identify metabolic biomarkers for adipocytic tumors, for accurate tumor classification.

METHOD AND MATERIALS

In a prospective study, de-identified human surgical samples were collected from subjects who underwent surgical resection of indeterminate adipocytic tumors (those with imaging features atypical for simple lipomas). Tissue samples were snap frozen and stored at -80°C until 1H MRS analysis. Dual phase solvent extraction was performed on approximately 300 mg of tumor tissue. The water phase was separated, freeze-dried, and reconstituted in 600ul D2O PBS for MRS analysis. All MR spectra were acquired on an Avance III 750 MHz (17.6T) Bruker NMR spectrometer. Computational modeling of pattern recognition based cluster analysis was utilized to look for significant differences in metabolic signatures between the adipocytic tumor types.

RESULTS

Tissue specimens from lipoma variants (n=6), ALTs (n=5) and adjacent non-involved subcutaneous normal fat (n=7) were examined using 1H MRS. Quantitative metabolite information is shown in figures 1A-B. The metabolic heatmap (Figure 1A) identifies the metabolic patterns of ALTs compared to lipoma variants and normal fat. A significant increase in several metabolite levels, including lactate, was observed in ALTs compared to lipomas and normal fat. Cluster analysis (Figure 1B) showed significant differences between normal fat, lipoma variants and ALTs.

CONCLUSION

Our preliminary data support investigating the use of high resolution 1H MRS of adipocytic tumors for differentiating between tumor subtypes and for understanding malignant progression.

CLINICAL RELEVANCE/APPLICATION

These results provide new insights into the metabolic differences between benign and premalignant tissue that may be exploited for formulating treatment plans and ultimately, metabolism-based therapeutic strategies.

SSA14-08 Radiomic Analysis of Peripheral Nerve Sheath Tumors Accurately Predicts Benign versus Malignant Status

PURPOSE

To evaluate whether radiomic analysis can accurately differentiate benign (BPNST) versus malignant peripheral nerve sheath tumors (MPNSTs), and compare it to the expert radiologist interpretation.

METHOD AND MATERIALS

44 patients with histologically confirmed PNSTs were identified from the institutional electronic data base. Fat suppressed T2W (fsT2W) imaging in isolation and all imaging combined including contrast (mimicking a routine setting) were used for Radiomic analysis and by two experienced musculoskeletal radiologists. Regions of interest (ROIs) corresponding to the tumor boundaries were contoured by a different experienced musculoskeletal radiologist using VelocityTM software (Varian Medical Systems). For system training, volumetric ROIs extracted from fsT2W images of 25 tumors (16 benign, 9 malignant) were used for the proposed Convolutional Neural Network (CNN), which included 7 convolution, 3 max-pooling and 2 fully connected layers. Data augmentation by rotating 3D images and Synthetic Minority Over-sampling technique (SMOTE) were employed to balance and increase training samples. The CNN was tested using 15 unknown tumors and evaluated for accuracy. Following which, two blinded radiologists in two diferent settings- fsT2W images (set 1) and all imaging sequences together (set 2) evaluated the same testing cases into benign versus malignant tumors. The accuracy of the CNN models was compared with radiologists. Statistical tests included Area Under the Curve (AUC) and Fisher's Exact Test.

RESULTS

The CNN model using fsT2W predicted benign versus malignant among PNSTs with an accuracy and AUC of 87% and 0.89, compared to the accuracy and AUC of 73%, 0.83 and 93%, 0.83 for the radiologists 1 and 2, respectively ($p>0.05$). The accuracy and AUC of radiologists 1 and 2, and CNN using all sequences including contrast imaging (mirroring the routine setting) was 71%, 0.81 and 71%, 0.70, and 93%, 0.94, respectively.

CONCLUSION

Radiomic analysis accurately differentiates benign versus malignant PNSTs and may serve as a powerful adjunctive measure during diagnosis of these neoplasms.

CLINICAL RELEVANCE/APPLICATION

Given the morbidity and mortality associated with MPNSTs, the high accuracy of radiomics is likely to be extremely valuable in their diagnostic work-up. Further study with larger cohorts can determine whether radiomics may aid in classification among BPNST subtypes, such as neurofibroma, schwannoma, and perineurioma.

PURPOSE

To determine the value of 3T magnetic resonance (MR) imaging texture analysis to differentiate high-grade from low-grade soft tissue sarcoma.

METHOD AND MATERIALS

The institutional review board approved this retrospective study and informed consent was waived. Forty-eight patients with soft tissue sarcoma who had undergone 3T MR imaging including contrast-enhanced (CE) imaging were included in this study. Texture analysis of whole tumor volume on T1- and T2-weighted images and fat-suppressed CE T1-weighted images were performed using Multiparametric toolbox. Histogram features (mean intensity, standard deviation (SD), skewness and kurtosis) and gray-level co-occurrence matrix features (Difference entropy, Difference variance, contrast, entropy) were compared between high-grade (grades 2 and 3) and low-grade (grade 1) soft tissue sarcoma using Mann-Whitney U test. The receiver operating characteristic curves with areas under the curve (AUC) for all parameters were obtained.

RESULTS

There were 11 patients with low-grade sarcomas and 37 patients with high-grade sarcomas: grade 2 (n = 10) and grade 3 (n = 27). T1 mean, T2 mean, T1 SD and CE T1 skewness were significantly lower in high-grade than low-grade sarcomas: 510.6 vs 761.3; 637.8 vs 850.0; 90.6 vs 142.9; 0.12 vs 0.63 (P= < .05), respectively. CE T1 mean, T2 skewness and CE T1 Difference variance were significantly higher in high-grade than low-grade sarcomas: 619.0 vs 385.9; 0.404 vs -0.425; 0.232 vs 0.175 (P= < .05), respectively. AUCs of above parameters except T1 mean were over 0.7: 0.725 (95% CI, 0.573-0.876) in T2 mean; 0.752 (95% CI, 0.568-0.936) in CE T1 mean; 0.737 (95% CI, 0568-0.906) in T1 SD; 0.722 (95% CI, 0.557-0.887) in T2 skewness; 0.722 (95% CI, 0.560-0.885) in CE T1 skewness; 0.706 (95% CI, 0.526-0.887) in CE T1 Difference variance. AUC of T1 mean was 0.698 (95% CI, 0.489-0.907).

CONCLUSION

Texture analysis based on 3T MR imaging may be reliable to differentiate between high-grade and low-grade soft tissue sarcomas.

CLINICAL RELEVANCE/APPLICATION

MR imaging texture analysis may help predict grade of soft tissue sarcoma.

PURPOSE

Although femoroacetabular impingement (FAI) describes a dynamic osseous abutment of the femur against the acetabulum, current standard imaging assessment is static. Recently CT-based impingement analysis was introduced whereas MRI would offer a radiation-free alternative. Thus we asked (1) what is the mean distance between surface points of 3D pelvis models derived from CT/MRI; (2) whether impingement free range of motion correlates between CT and MRI; (3) and whether zones of impingement match for 3D models based on CT and MRI?

METHOD AND MATERIALS

IRB-approved comparative, retrospective study of 20 symptomatic hips with FAI. 3D CT scans (isovoxel: 1mm3) of the entire pelvis and the distal femoral condyles were obtained. Preoperative MR arthrograms of the hip were obtained including 0.8mm3 isovoxel T1 3D VIBE- and 1mm3 isovoxel 3D T1 VIBE DIXON sequences of the entire pelvis and the distal femoral condyles. Threshold-based manual segmentation was performed using commercial software (AMIRA). Both 3D models were compared with inhouse developed software which includes two specific algorithms for detection of the acetabular rim and for detection of the center of roation. We calculated (1) percentage of the surface points with < 1mm difference between the CT-/MR-based 3D models; (2) assessed correlation of impingement-free range of motion (in: flexion; extension; internal rotation 90° of flexion; external rotation in 90° of flexion; abduction; adduction) between CT and MRI and (3) compared location of impingement zones between CT and MRI using the clock-face system which divides the femur and acetabulum into 12 'hour' positions.

RESULTS

(1) 83% and 79% of the surface points of the proximal femur respectively of the acetabulum differed <1mm between the CT-based and MRI-based 3D models. (2) Correlation for the range of motion values was excellent (spearman rho=0.993, p<0.05) between CT and MRI. (3) Location of impingement did not differ between CT-based and MRI-based range of motion analysis in 12/12 acetabular and 11/12 femoral clock-face positions.

CONCLUSION

MRI-based 3D models of the pelvis can replace CT-based 3D models for range of motion analysis in femoroacetabular impingement

CLINICAL RELEVANCE/APPLICATION

3D-MRI based impingement analysis of the hip is a further step towards non-invasive, personalized surgical planning of FAI especially for complex deformities such as abnormal femoral torsion.

SSA15-02 Does 3DMR Provide Equivalent Information as 3DCT for the Pre-Operative Evaluation of Adult Hip Pain Conditions of Femoroacetabular Impingement and Hip Dysplasia?

Kevin.Yan@UTSouthwestern.edu

PURPOSE

Femoroacetabular impingement (FAI) and hip dysplasia (HD) are frequently evaluated by isotropic CT (3DCT) for preoperative planning at the expense of radiation. The aim was to determine if isotropic MRI (3DMR) imaging can provide similar quantitative and qualitative morphological information as 3DCT.

METHOD AND MATERIALS

25 consecutive patients with a final diagnosis of FAI or HD were retrospectively selected from December 2016-December 2017. Two readers (R1, R2) performed quantitative angular measurements on 3DCT and 3DMR, blinded to the diagnosis and each other's measurements. 3DMR and 3DCT of the hips were qualitatively and independently evaluated by a radiologist (R3), surgeon (R4), and fellow (R5). Interobserver and intermodality comparisons were performed.

RESULTS

Quality was good to excellent on all 3DCT and 3DMR reconstructions. The ICC was good to excellent for all measurements between R1 and R2 (ICC: 0.60-0.98) and the majority of intermodality measurements for R1 and R2. Average inter-reader and inter-modality PABAK showed good to excellent agreement for qualitative reads. On CT, all alpha angles (AA) were significantly lower in dysplasia patients than in cam patients ($p<0.05$). Lateral center-edge angle (LCEA) at the anterior, center, and posterior acetabulum were significantly lower in dysplasia than in cam patients ($p<0.05$). On MR, AA at 12, 1, and 2 o'clock, and LCEA at center were significantly lower in dysplasia patients than in cam patients ($p<0.05$).

CONCLUSION

Strong interobserver and intermodality correlations of hip morphology suggest that 3DMR has good potential to replace 3DCT and serve as a one-stop modality for bone and soft tissue characterizations in the pre-operative evaluation of FAI and HD.

CLINICAL RELEVANCE/APPLICATION

In patients with symptomatic FAI and HD, 3DMR can replace 3DCT in the pre-operative evaluation, thereby reducing radiation, time, cost, and discomfort for the patients.

SSA15-03 MR Texture Analysis of Acetabular Subchondral Bone Can Discriminate Between Normal and Cam Positive Hips

Sunday, Nov. 25 11:05AM - 11:15AM Room: E353B

Participants

Kawan S. Rakhra, MD, Ottawa, ON (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To assess whether texture analysis of acetabular subchondral bone on MRI can differentiate between normal and cam positive hips.

METHOD AND MATERIALS

IRB-approved, retrospective case-control study analyzing MR images in subjects with and without cam morphology of the proximal femur (n=68: 19 controls, 25 asymptomatic cam and 24 symptomatic cam-FAI). All subjects underwent unilateral 1.5T hip MRI. The acetabular subchondral bone was contoured manually as a volume of interest (VOI) on sagittal PD images. 3D histogram and second order texture features were evaluated for the global acetabular VOI for each subject using MaZda (v4.6). Differences between controls and asymptomatic or symptomatic cam hips were explored using Mann-Whitney U tests with post-hoc Bonferroni correction. Intra-acetabular variations in texture were assessed by subdividing each VOI into anterior and posterior segments in the sagittal plane and into medial, middle, and lateral segments in the coronal plane, generating 6 ROIs. Between groups and within-subjects differences in texture features were assessed using mixed model ANOVAs. Features were used to train a series of gradient boosted regression trees; for each, 500 hyperparameter configurations were selected at random. 10-fold, stratified cross-validation was then performed and the accuracy of the 10 forests for identifying cam positive hips was averaged.

RESULTS

Both asymptomatic and symptomatic cam-FAI hips demonstrated higher gray-level variance and lower kurtosis compared to controls ($p=0.003$ for each). Gray-level co-occurrence features f3, f4, and f7 were significantly higher in cam positive hips compared to controls ($p<=0.003$ for each). Sub-region analysis revealed no significant interactions between subject group and ROI. The post-validation classification accuracy achieved by each gradient boosted tree model was 72% (control vs asymptomatic) and 79% (control vs symptomatic cam-FAI).

CONCLUSION

Texture features extracted from MRI can detect subtle differences in subchondral bone architecture between controls and cam positive hips, regardless of patient symptom status.

CLINICAL RELEVANCE/APPLICATION

The texture profile of acetabular subchondral bone in cam positive hips is significantly different from controls in all regions. This suggests there are extra-articular structural changes occurring globally within the acetabular subchondral bone of patients with cam morphology regardless of symptom status.

SSA15-04 Postoperative, Traction MR Arthrography in Patients with Persisting Pain After Hip Arthroscopy for FAI Reveals Unexpected High Prevalence of Osseous Deformities and Intra-Articular Lesions Due to Under-/ or Overcorrection

Sunday, Nov. 25 11:15AM - 11:25AM Room: E353B

Ehrenfried Schmaranzer, St. Johann in Tirol, Austria (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Numbers of hip arthroscopies for FAI correction have risen exponentially, leading to an increase of patients with persistent pain who undergo postoperative MR imaging. To assess prevalence of new/residual (1) osseous deformities, (2) intra-articular lesions and (3) progression of osteoarthritis in symptomatic patients undergoing pre- and postoperative MR imaging after hip arthroscopy.

METHOD AND MATERIALS

IRB-approved, retrospective study. Between 2010-17, 806 patients underwent arthroscopic FAI correction and/or labrum surgery. Database was reviewed for symptomatic patients with complete radiographs and traction MR arthrography (MRA) of the hip (1.5 T) obtained before and after hip arthroscopy according to the routine protocol. 49 patients were included: mean age 29 ± 10 years, 67% female. Traction was applied using a MR-compatible traction device with weight-adaption. One reader assessed pre- and postoperative images. (1) Acetabular coverage (LCE<25° = dysplasia, LCE>39° = pincer deformity) and Tönnis osteoarthritis (OA) grade were assessed on AP pelvic views. Cam deformity was defined (a>60°) on radial MR images. Femoral torsion measurements were only available for postoperative MRI (low/high torsion: <5°/>30°). (2) Presence of residual tears-, retears of the labrum, capsular adhesions/defects was assessed on traction MRA. (3) OA progression on traction MRA was defined as new acetabular/femoral cartilage lesions and osteophytes formation.

RESULTS

(1) Preoperatively 42 (86%) hips showed deformities: 2 (4%) dysplastic-, 11 (22%) pincer- and 39 (80%) cam deformities. Postoperatively 39 (80%) hips showed deformities; 9 (18%) dysplastic-, 8 (16%) pincer-, 20 (41%) cam deformity, 4 (8%) hips with torsion <5°, 10 (20%) hips with torsion >30°. (2) Postoperatively 14 (29%) cases with residual-, 12 (24%) cases with labrum retears were observed. 6 (12%) hips had capsular adhesions, 22 (45%) had capsular defects. (3) Radiographic OA progression was observed in 5 (10%) hips, in 14 (30%) hips on traction MRA.

CONCLUSION

Prevalence of osseous deformities due to over- or undercorrection and intra-articular lesions is high after failed hip arthroscopy. Traction MRA was useful for detection of OA progression.

CLINICAL RELEVANCE/APPLICATION

Identification of osseous over-/undercorrection after failed hip arthroscopy is essential because open surgical approaches must be considered for correction of dysplasia and abnormal femoral torsion.

SSA15-05 Comparison of Lateral Centre Edge Angle and Sourcil Angle Measurements on "Ghost" 3D Volume Rendered CTs and Plain Radiographs

PURPOSE

Comparison of lateral centre edge angle and sourcil angle measurements on "Ghost" 3D volume rendered CTs and plain radiographs.

METHOD AND MATERIALS

A retrospective single-centre observational study evaluating the degree of agreement between measurements of lateral centre edge angle on CT and plain radiographs in 50 hips. Measurements of LCEA and sourcil angle were made on AP radiographs and 'Ghost' CT. All patients who were under orthopaedic investigation for femoro-acetabular impingement, had both a pelvic radiograph

and CT of at least one hip were included. Patients with severe anatomic deformity or those who were post-operative were excluded from the study. A paired sample t-test was performed to determine if there was a significant difference between measurements on plain radiograph and 'Ghost' CT, with the null hypothesis stating no significant difference.

RESULTS

On plain film the mean of the LCEA was 31.60, standard deviation = 8.254; and on CT "Ghost" images the mean LCEA was 30.96, standard deviation = 8.315 (paired t-test: $p < .002$). The confidence interval is 0.25 to 1.03. On plain film the mean of the Sourcil angle was 6.20, standard deviation = 4.848; and on CT "Ghost" images the mean of LCEA was 6.76, standard deviation = 4.841 (paired t-test: $p < .016$). The confidence interval is -1.19 to -1.17. The results show that there is a statistical difference between measurements of LCE and sourcil angles made on plain radiographs and CT, but the confidence interval is small. We can be 95% sure that the true mean angle lies within a range of 1.28 degrees for lateral centre edge angle and a range of 0.02 degrees for the sourcil angle.

CONCLUSION

Although there is a statistical difference between measurements of LCE and sourcil angles made on plain radiographs and "Ghost" CT the narrow confidence interval infers that the difference is actually quite small and in clinical practice this would be clinically insignificant. This would preclude the need for plain radiographs and reduce the radiation dose in young patients who ultimately require CT imaging as part of their femoro-acetabular impingement workup.

CLINICAL RELEVANCE/APPLICATION

Measurements of LCEA and sourcil angles on 'Ghost CT' are clinically indifferent and can be used to preclude the need for plain radiographs in the work up of FAI in young patients with hip pain.

SSA15-06 The Puck Stops Here: An Adaptive Response of the Hip Observed with MRI and Unique to Super External Rotators

Sunday, Nov. 25 11:35AM - 11:45AM Room: E353B

Participants
Matthew Bober, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose
Adam C. Zoga, MD, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

matthew.bober@jefferson.edu

PURPOSE

Overhead athletes rely on extreme ranges of motion to excel in their respective fields, leading to structural changes including capsular and osseous overgrowth, which in turn contribute to overuse lesions including SLAP and unique impingement syndromes. Super external hip rotators, in particular hockey goalies, similarly rely on tremendous ranges of motion to excel at their avocation. We sought to compare hip capsule thickness in hockey goalies with age and gender matched controls in order to describe MRI findings of adaptive response of the hip.

METHOD AND MATERIALS

Retrospective cohort study examining the hip capsule thickness of hockey goalies with other male athletes aged matched at 20-30 years. Capsule thickness was used as a marker for adaptive response at the hip as this was described previously with adaptive response in the shoulder. Power analysis was performed and determined that a sample size of 17 was selected for each group. Measurements were performed at the anterior, middle, and posterior capsule regions on coronal non-fat saturated T1 MRI images at the level of the femoral head and neck. A two tailed t-test was then conducted to analyze the two groups.

RESULTS

The hip capsule was statistically thicker in super external rotators at each region when compared with other age matches athletic males. The average capsule thickness at the femoral head in the control group ranged from 8 - 9 mm and in the goalies group from 10 - 12 mm (p values ranged from 0.001 and 0.007). At the femoral neck, the control group capsule thickness was between 11 - 13 mm compared to 16 - 18 mm for the super external rotators (p-values between 0.002 and 0.01).

CONCLUSION

Hip super external rotating hockey goalies have a thicker hip capsule than their age and gender matched controls at both the level of the femoral head and neck.

CLINICAL RELEVANCE/APPLICATION

Hip super external rotators adapt with capsular thickening, which may predispose to hip pathology known to be prevalent in such athletes such as femoroacetabular impingement, labral tears, and early osteoarthritis. This adaptive hip capsular thickening should be observed at MRI, and should be correlated with other pathologies on a larger scale with a goal of prevention and early intervention.

SSA15-07 Diagnostic Performance of Magnetic Resonance Imaging in Detecting Syndesmotic Injuries: A Meta-Analysis

sdemehr1@jhmi.edu

PURPOSE

Distal tibiofibular syndesmotic injuries are common and occur in association with ankle sprains and ankle fractures. There are conflicting reports in the literature regarding the diagnostic performance of magnetic resonance (MR) imaging in detecting these injuries. Therefore, in this meta-analysis we intend to determine diagnostic performance of MR-imaging in detecting syndesmotic injuries, using open or arthroscopic surgery as the standard of reference.

METHOD AND MATERIALS

A comprehensive literature search (until March 2018) was performed and original research studies reporting diagnostic performance of MRI and MR arthrography (MRA) in detecting syndesmotic injuries were included. Pooled values of sensitivity and specificity were calculated using fixed or random effect models based on the level of heterogeneity.

RESULTS

Out of 421 identified records, seven studies (309 MRI examinations) were included. Two studies (65 ankles) also reported the results of indirect MRA (iMRA) while other two studies (53 ankles) reported the results of direct MRA. There was no publication bias according to Deeks funnel plot asymmetry test (P=0.2) and meta-funnel. Pooled values of sensitivity were 89% [95% confidence interval (CI): 84%-94%] for non-enhanced MRI, 91% (CI: 79%-98%) for iMRA and 92% (CI: 73%-99%) for MRA. Pooled values of specificity of MRI, iMRA and MRA were 88% (CI: 82%-93%), 91% (CI: 82%-96%) and 67% (CI: 35%-90%), respectively. High degree of heterogeneity was observed in all modalities (I2 >50%). Comparing diagnostic odds ratios (DOR) of MRI with iMRA yielded no significant result (relative DOR (rDOR):0.41, P=0.5). No significant difference was observed between DORs of MRI and MRA (rDOR: 1.76, P=0.4). There was no significant difference between DORs of iMRA and MRA (rDOR: 7.69, P=0.2).

CONCLUSION

MRI, iMRA and MRA can accurately detect syndesmotic injuries. The specificity of MRA appeared to be lower when compared to MRI and iMRA.

CLINICAL RELEVANCE/APPLICATION

With high diagnostic performance of conventional non-enhanced MRI, using intravenous or intraarticular gadolinium may not improve the diagnostic performance of MRI examinations.

SSA15-08 Scanned versus Fused-Reconstructed Oblique MR-Images for Assessment of the Ankle Syndesmosis: Diagnostic Performance and Reader Agreement

peter.dankerl@uk-erlangen.de

PURPOSE

To evaluate the diagnostic performance and reader agreement of a novel image reconstruction method enabling fusion of standard two-dimensional transversal and coronal images into oblique images for the assessment of the ankle syndesmosis.

METHOD AND MATERIALS

We evaluated 40 magnetic resonance imaging examinations of patients with ankle sprains (16 with ruptures and 24 without) for the presence of anterior inferior tibiofibular ligament rupture. For all patients, an oblique-fusion reconstruction (OFR) was created in comparable fashion to the scanned oblique proton density weighted turbo spin echo (PDwTSE) sequence. Image reconstruction was performed with dedicated software enabling image fusion from standard transversal 3 mm PDwTSE and coronal sequences with fat suppression. The resulting fused images were used as the source for the reconstruction of OFR images. To evaluate diagnostic

performance, three readers with different levels of experience independently read the scanned images once and the fused images twice. We analyzed sensitivity, specificity, negative and positive predictive values, accuracy and agreement.

RESULTS

The experienced reader misinterpreted one OFR as false negative, demonstrating a sensitivity of 0.97 and specificitiy of 1.00. The intermediate reader had perfect accuracy. The inexperienced reader diagnosed two false positive ruptures (specificity: 0.92) in his first, and missed three ruptures (sensitivity: 0.81) in his second read. No differences were significant. Intrareader agreement was 0.95, 1.00 and 0.74 and interreader agreement was 0.90.

CONCLUSION

The proposed OFR enables reliable detection of anterior inferior tibiofibular ligament rupture with excellent inter- and intrareader agreement, making conventional scanning of oblique images redundant.

CLINICAL RELEVANCE/APPLICATION

Presented method enables the creation of additional MRI sequences in a totally different orientation from routine 2D images. Thereby scanning of e.g. oblique images is redundant and MRI scanning time - in our case 28% can be saved.

SSA15-09 Tarsal Coalition and the Accessory Anterolateral Facet

Sunday, Nov. 25 12:05PM - 12:15PM Room: E353B

Participants
Mashya T. Abbassi, MD, Richmond, VA (*Presenter*) Nothing to Disclose
Josephina A. Vossen, MD, PhD, Richmond, VA (*Abstract Co-Author*) Nothing to Disclose
Peter J. Haar, MD, PhD, Richmond, VA (*Abstract Co-Author*) Nothing to Disclose
Kevin B. Hoover, MD, PhD, Richmond, VA (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

The accessory anterolateral talar facet (AALTF) is an anatomic variant that can cause peroneal spastic flatfoot in adolescents and accessory talar facet impingement (ATFI) in adults. The purpose of this study was to assess the relationship between AALTF and tarsal coalitions.

METHOD AND MATERIALS

Retrospective analysis of consecutive patients undergoing MRI ankle over a 2-year period (01/2014 to 12/2015) at our institution was performed. This study received IRB approval and complied with HIPAA guidelines. We reviewed MRIs for presence of AALTF and tarsal coalition. The criteria for identifying AALTF on MRI was facet articulation spreading contiguously from the posterior facet of the talus anterior to the lateral process of the talus. Presence of a tarsal coalition was assessed using MRI, allowing differentiation between types of coalition (cartilaginous, fibrous and osseous). Exclusion criteria were prior surgery, recent trauma, or abnormalities preventing visualization of the talocalcaneal joint.

RESULTS

Of the 391 patients (137 men, 254 women; mean age 45 years) included in this study, 3.6% (14/391) had an AALTF. Of these patients, 29% (4/14) had a tarsal coalition, of which 3 were talocalcaneal (1 osseous, 1 fibrous and 1 cartilaginous) and 1 was calcaneonavicular (fibrous). Of the patients without an AALTF, 2% (9/377) had a tarsal coalition, of which 7 were calcaneonavicular (4 fibrous and 3 cartilaginous), 2 were talocalcaneal (1 osseous, 1 fibrous). One-tailed chi-square tests of independence with Yates correction and odds ratio (OR) calculations were performed to examine the relation between the AALTF and the presence of a tarsal coalition. For the relationship between AALTF and tarsal coalition, $\chi 2 = 21.2$ (df, 1; n = 391; $p < 0.0001$; OR 16.3; 95% CI, 4.3-62.1).

CONCLUSION

Our study showed a significant relationship between the presence of an AALTF and tarsal coalition. Our findings indicate that MRI is a valuable test for identifying comorbid findings of AALTF in patients.

CLINICAL RELEVANCE/APPLICATION

The accessory anterolateral talar facet (AALTF) is an anatomic variant that can cause peroneal spastic flatfoot and accessory talar facet impingement (ATFI). Our study showed a significant relationship between the presence of an AALTF and tarsal coalition. Patients undergoing resection for tarsal coalition should be evaluated for AALTF, in order to improve pre-operative planning and postsurgical outcome.

knichols@northwell.edu

PURPOSE

Left ventricular (LV) arteries are considered abnormal if stenosis > 70%, but lesser stenoses may be concerning. Our study was undertaken to determine the % of cases in which stenoses are < 70% & perfusion images suggest apparently normal (ApNl) arteries, yet myocardial flow reserve (MFR) is abnormally low, & whether PET parameters predict magnitude of stenosis.

METHOD AND MATERIALS

Data were analyzed of 105 pts evaluated by Rb-82 rest/regadenoson-stress PET/CT & arteriography, which measured % stenoses. Global ejection fractions (EFs) & regional summed stress score (SSS) & summed rest score (SRS) of relative myocardial perfusion were assessed. Rest & stress systolic & diastolic asynchrony (Asynch) was assessed by a medical imaging physicist who visually scored phase histograms & phase polar maps within a coronary territory using a 5-point scale (0 = normal to 4 = markedly asynchronous extensive territory), based on phase polar maps being out of phase from expected contraction patterns of normal pts. Absolute myocardial blood flow (MBF) was quantified from rebinned first pass dynamic transit images of the Rb-82 bolus injection through the heart chambers, with myocardial flow reserve (MFR) computed as stress-MBF/rest-MBF. ApNl arteries were defined as those with SRS < 4 & SSS < 4 & stenosis < 70%. Following convention, abnormal regional MFR was defined as < 2.0.

RESULTS

Among 315 arteries, 174 had undetectable stenosis, 72 ranged from 25-69% & 69 ranged from 70-100%. Among all arteries, 162 were ApNl with higher MFR than the other 153 arteries (2.65±1.34 versus 1.96±1.26, $p < 0.0001$). Nonetheless, 35% (56/162) of ApNl arteries had abnormally low MFR < 2.0 (mean = 1.50±0.31). For all arteries, magnitude of % stenosis was most strongly associated with magnitude of Asynch ($r = 0.50$, $p < 0.0001$), & significantly associated with stress MBF ($r = -0.25$, $p < 0.0001$), SSS ($r = 0.24$, $p < 0.0001$), SRS ($r = 0.17$, $p = 0.002$), & MFR ($r = -0.18$, $p = 0.002$). For ApNl arteries, % stenosis was associated with magnitude of Asynch ($r = 0.34$, $p < 0.0001$).

CONCLUSION

In arteries that are apparently normal by relative perfusion assessment & by conventional arteriographic criteria, MFR can nonetheless by abnormally low, with stenoses < 70% associated with regional asynchrony.

CLINICAL RELEVANCE/APPLICATION

It is advisable to measure regional MFR & regional asynchrony for pts with suspected CAD.

SSA16-02 Evaluation of Role of F-18 FDG Cardiac PET and Tc-99m Sestamibi Myocardial Perfusion Imaging in Assessing the Therapeutic Benefit in Patients with Coronary Artery Disease and Left Ventricular Systolic Dysfunction

PURPOSE

To evaluate the therapeutic benefit with revascularization and optimal medical treatment (OMT) in patients diagnosed with hibernating myocardium on myocardial perfusion imaging (MPI) using F-18 FDG cardiac PET

METHOD AND MATERIALS

59 consecutive patients (43 males, 16 females, Mean Age 60.7 ± 9.4 years) with CAD and LV systolic dysfunction who underwent myocardial viability imaging for revascularization work-up and were diagnosed with hibernating myocardium were enrolled in this study. Patients were later treated with either revascularization or OMT and were followed for a median duration of 7.7 months for assessing the therapeutic benefit. Therapeutic benefit was assessed under 3 categories (a) Improvement in functional class (b) Adverse cardiac-events and (c) Improvement in LV function and myocardial perfusion on follow-up resting 99mTc-sestamibi myocardial perfusion imaging.

RESULTS

29 patients underwent revascularization (49%) and 25 patients received OMT (42%). Five patients were lost to follow-up. Patients were matched for baseline characteristics in both treatment arms. On follow-up, significant improvement was noted in NYHA functional class and CCS angina class post-revascularization. No such improvement was noted in the OMT group. The cardiac-event rate of patients in OMT group was significantly higher than that of patients in revascularization group (36% vs. 10.3 %; p = 0.046). At 1 year of follow-up, event-free survival in revascularization group was significantly superior compared to OMT group (83.8% vs. 50.8%; p= 0.039). On follow-up resting MPI scan, mean improvement in LVEF in revascularization group was significantly higher than in OMT group (6.0% vs. 1.4%; p=0.04).

CONCLUSION

Myocardial viability imaging is a sensitive modality to identify hibernating myocardium in patients with CAD and LV dysfunction and predicting its recovery following revascularization, thereby guiding the optimal treatment strategy for these patients.

CLINICAL RELEVANCE/APPLICATION

Myocardial viability imaging should be performed prior to revascularization in patients with coronary artery disease with left-ventricular dysfunction to help predict recovery post-treatment.

SSA16-03 A Comparative Analysis of Myocardial Perfusion on Gated SPECT versus Coronary Atherosclerosis and Calcium Score on 64-Slice CT

Sunday, Nov. 25 11:05AM - 11:15AM Room: S505AB

Participants
Parul Mohan, MBBS, MD, New Delhi, India (*Abstract Co-Author*) Nothing to Disclose
Harsh Mahajan, MD, MBBS, New Delhi, India (*Presenter*) Nothing to Disclose
Upendra Kaul, MBBS, MD, New Delhi, India (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

drparulmohan@gmail.com

PURPOSE

The aim of the current study was to compare the results of 64-slice CT and gated SPECT on a regional basis (per vessel distribution territory) in patients with known or suspected CAD.

METHOD AND MATERIALS

Three hundred and seventy five patients underwent both gated SPECT for myocardial perfusion imaging and 64-slice CT for coronary calcium scoring and coronary angiography. The coronary calcium score was determined for each coronary artery. Coronary arteries on multislice CT angiography were classified as having no CAD, insignificant stenosis (<50% luminal narrowing),significant stenosis, or total or subtotal occlusion (>90% luminal narrowing).Gated SPECT findings were classified as normal or abnormal (reversible or fixed defects) and were allocated to the territory of one of the various coronary arteries.

RESULTS

In coronary arteries with a calcium score of 10 or less, the corresponding myocardial perfusion was normal in 96 %. In coronary arteries with extensive calcifications (score > 400), the percentage of vascular territories with normal myocardial perfusion was lower, 48%. Similarly, in most of the normal coronary arteries on 64-slice CT angiography, the corresponding myocardial perfusion was normal on SPECT in >94%. In contrast, the percentage of normal SPECT findings was significantly lower in coronary arteries with obstructive lesions (<57%) or with total or subtotal occlusions (<10%) (P < 0.01). Nonetheless, only 42% of vascular territories with normal perfusion corresponded to normal coronary arteries on multislice CTangiography, whereas insignificant and significant stenosis were present in, respectively, 40% and 18% of corresponding coronary arteries.

CONCLUSION

Although a relationship exists between the severity of CAD on multislice CT and myocardial perfusion abnormalities on SPECT, analysis on a regional basis showed only moderate agreement between observed atherosclerosis and abnormal perfusion. Accordingly, 64-slice CT and gated SPECT provide complementary rather than competitive information, and further studies should address how these two modalities can be integrated to optimize patient management.

CLINICAL RELEVANCE/APPLICATION

Accordingly, 64-slice CT and gated SPECT provide complementary rather than competitive information.

SSA16-04 The Association of Carotid Plaque 18F-FDG and 18F-Naf Uptake on PET Scan with Symptomatic Carotid Artery Disease: A Systematic Review and Meta-Analysis

PURPOSE

We sought to investigate the ability of 18F-FDG and 18F-NaF PET imaging to identify vulnerable carotid plaques and predict stroke recurrence in the setting of recent cerebrovascular accidents by performing a systematic review.

METHOD AND MATERIALS

We performed this study according to the Meta-Analysis of Observational Studies in Epidemiology (MOOSE) group and the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement guidelines. We performed a systematic review of Ovid MEDLINE, Ovid EMBASE, and the Cochrane Library Databases yielding a total of 4,144 unique articles for screening after de-duplication. These were screened for peer-reviewed journal articles that examined the association between carotid plaque tracer uptake and recent or future ischemic events such as strokes, transient ischemic attacks and retinal artery embolisms. Screened articles were then adjudicated as meeting inclusion criteria by two independent readers.

RESULTS

Fourteen articles were included for subsequent analysis. Of those, 11 articles analyzed 18F-FDG uptake in recently symptomatic carotid arteries as compared to asymptomatic carotid arteries. Two of these studies analyzed 18F-NaF uptake as well. The remaining 3 articles investigated the risk of stroke recurrence associated with 18F-FDG uptake. The existing literature demonstrates significant heterogeneity in the PET protocols, reported tracer uptake metrics, and thresholds for positive uptake.

CONCLUSION

Our systematic review revealed a growing body of literature supporting 18F-FDG's utility in predicting future stroke recurrence and its modest ability in discerning symptomatic from asymptomatic carotid plaques. Additional studies are needed to elucidate the role of 18F-NaF as compared to 18F-FDG imaging. Further work is needed to define more standardized approaches for PET image acquisition and imaging analysis in order to improve the generalizability of this technique to detect high-risk carotid plaques.

CLINICAL RELEVANCE/APPLICATION

Carotid atherosclerosis is responsible for 15% of ischemic strokes. Further work is needed to investigate the utility of 18F-FDG and 18F-NaF PET imaging in detecting high-risk carotid plaques.

SSA16-05 Provider Utilization Trends for Elective Myocardial Perfusion Imaging

sarah.kamel@jefferson.edu

PURPOSE

To analyze trends in performance of elective stress nuclear myocardial perfusion imaging (MPI) modalities in the Medicare population.

METHOD AND MATERIALS

The nationwide Medicare Part B fee-for-service databases for 2004-2016 were reviewed. CPT codes relevant to stress MPI were selected: planar and single photon emission computed tomography (SPECT), and positron emission computed tomography (PET). The databases indicate procedure volume for each code, and these were used to calculate utilization rates per 1,000 Medicare beneficiaries. Elective MPI exams were identified by using place-of-service codes for private offices and hospital outpatient departments (HOPDs). The specialty of the performing physician was determined using Medicare physician specialty codes. Because the Medicare Part B databases are complete population counts, sample statistics are not required.

RESULTS

Elective standard (STD) MPI (both planar imaging and SPECT) utilization peaked in 2006 at 74 studies per 1,000 beneficiaries and then progressively decreased to 45 by 2016 (-36%). In 2004, cardiologists' share of elective STD MPI had been 79%, and this steadily increased in subsequent years to 87% in 2016. Cardiologists perform elective STD MPI mostly in private offices where

utilization peaked in 2008 at 50 studies per 1,000 and then declined to 22 in 2016 (-56%). In HOPDs, utilization by cardiologists has increased over the period of the study from 7 studies to 15 (+120%). Utilization in private offices and HOPDs by radiologists has declined from 13 in 2004 to 6 in 2016 (-58%). Elective PET MPI, less frequently used at 3 studies per 1,000 in 2016, maintained an overall net upward trend since 2005, and most of this growth reflected increasing use by cardiologists (90% share in 2016).

CONCLUSION

In the Medicare population, the overall use of elective STD MPI is declining, however cardiologists are performing an increasing market share in the outpatient setting. A shift in place-of-service has been noted with fewer studies performed in private offices and increasing numbers performed in HOPDs. PET MPI utilization, while still not widespread, has grown over the period of the study, reflecting an increasing use by cardiologists.

CLINICAL RELEVANCE/APPLICATION

Cardiologists maintain an increasing share in utilization of elective standard and PET MPI.

SSA16-06 Medium and Large Vessel Vasculitis: Recognizing Patterns on FDG PET-CT

vidur@mahajanimaging.com

PURPOSE

The diagnosis of medium to large-vessel vasculitis and the assessment of its activity and extent remain challenging. We assess the clinical utility of FDG PET CT in patients with suspected medium and large vessel vasculitis to evaluate the pattern and extent of vessel involvement.

METHOD AND MATERIALS

100 consecutive patients (64 males and 36 females) with suspected medium and large-vessel vasculitis were evaluated with FDG PET/CT. FDG uptake in the major vessels was visually graded using a four-point scale and quantified with standardised uptake values (SUV max). Patients were further sub-divided into three groups: (a) steroid-naive medium to large-vessel vasculitis (N=34, 69% of total positive patients), (b) vasculitis on steroid treatment (N=15, 30.6% of total positive patients) and (c) no evidence of vasculitis (N=51). Analysis of variance and linear regression were used to investigate the association of FDG uptake with clinical parameters.

RESULTS

FDG-PET revealed pathological findings in 49 of 100 patients. FDG PET/CT was positive (visual uptake >2; equal to or greater than liver) in all patients with steroid-naive medium to large-vessel vasculitis. The thoracic aorta, the carotid and the subclavian arteries were most frequently involved. In these patients, SUVmax values were significantly higher than in the other groups.

CONCLUSION

FDG PET is a sensitive and specific imaging tool for medium and large vessel vasculitis, especially when performed in steroid naive patients. It increases the overall diagnostic accuracy and has an impact on the clinical management in a significant proportion of patients.

CLINICAL RELEVANCE/APPLICATION

FDG-PET should be used in diagnosis and characterisation of medium and large vessel vasculitis to determine optimal treatment methodologies.

SSA16-07 Assessing the Feasibility of 18F-Naf PET/CT to Detect the Atherosclerotic Calcification of Aortic Wall in Rheumatoid Arthritis Patients

siavash.mehdizadehseraj@uphs.upenn.edu

PURPOSE

Rheumatoid arthritis (RA) has long been associated with increased risk for atherosclerosis. 18F-sodium fluoride (NaF) is a PET tracer that detects calcium deposition in the early stages of atherosclerotic plaque formation. We aimed to assess whether NaF-PET/CT can sensitively discriminate aorta calcification between RA patients and normal subjects.

METHOD AND MATERIALS

Fifteen RA patients (11 men, 4 women; mean age 53.8±10.8 y, range 25-64) and fifteen healthy controls (11 men, 4 women; mean age 53.5±11.2 y, range 25-64) were included in this study. Controls were matched to patients by sex and age (±5 years). All subjects in this study underwent NaF-PET/CT scanning 90 minutes after NaF tracer administration. Using OsiriX software, regions of interest were manually drawn around the abdominal aorta wall starting superiorly with the first axial slice containing the left kidney, ending with the last slice before the aortic bifurcation. The global mean standardized uptake value (global SUVmean) was obtained and compared between RA patients and healthy subjects. An unpaired t-test assessed the difference in means of RA group and controls, and a ROC analysis assessed discrimination.

RESULTS

The global SUVmean of RA patients ranged from 0.88 to 2.35, and from 0.79 to 1.47 in healthy controls. Furthermore, average global SUVmean scores among RA patients was significantly greater than that of healthy controls. (1.62±0.49 and 1.04±0.16, respectively, $P<0.01$). ROC analysis revealed fair discrimination between the two groups (AUC = 0.77).

CONCLUSION

Our findings indicate that global assessment with NaF-PET/CT is a feasible technique to detect active vascular calcification in the abdominal aorta. Discriminant validity was observed by assessing a known co-morbidity of RA and comparing RA to non-RA. Further studies are needed to validate this technique to diagnose and monitor patients at high risk for atherosclerosis.

CLINICAL RELEVANCE/APPLICATION

Global assessment with NaF-PET/CT can determine the degree of active vascular calcification, which can help diagnose, monitor, and assess treatment response in atherosclerosis.

SSA16-08 F-18 FLT PET/CT for Therapeutic Monitoring in Patients with Cardiac Sarcoidosis: Comparison with F-18 FDG PET/CT

Sunday, Nov. 25 11:55AM - 12:05PM Room: S505AB

Participants
Takashi Norikane, Kita-gun, Japan (*Presenter*) Nothing to Disclose
Yuka Yamamoto, MD, PhD, Kagawa, Japan (*Abstract Co-Author*) Nothing to Disclose
Takahisa Noma, Kita, Japan (*Abstract Co-Author*) Nothing to Disclose

Yoshihiro Nishiyama, MD, Kagawa, Japan (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

F-18 fluorodeoxyglucose (FDG) PET has been used in sarcoidosis including cardiac involvement for therapeutic monitoring. However, it can be challenging because it accumulates physiologically in normal myocardium. The purpose of this study was to evaluate the ability of F-18 fluorothymidine (FLT) PET for therapeutic monitoring in patients with cardiac sarcoidosis, in comparison with FDG.

METHOD AND MATERIALS

FLT and FDG PET/CT studies were performed before and after immunosuppressive therapy in 6 patients with newly diagnosed cardiac sarcoidosis. The patients had fasted for at least 18 h before FDG PET/CT, but were given no special dietary instructions before FLT PET/CT. Uptake of FLT and FDG was examined visually and semiquantitatively using maximal standardized uptake value (SUV).

RESULTS

Before therapy, all patients had both cardiac and extra-cardiac thoracic sarcoidosis. Fifteen lesions in cardiac region and 22 lesions in extra-cardiac region were visually detected on both FLT and FDG PET/CT. After therapy, 10 and 8 lesions in cardiac region and 15 and 11 lesions in extra-cardiac region showed no increased uptake on FLT and FDG PET/CT, respectively. On after therapy FLT scan, all SUV for each lesion were lower than those on before therapy FLT scan, and the mean SUVs in cardiac and extra-cardiac lesions decreased significantly ($p<0.001$ and $p<0.001$, respectively). On after therapy FDG scan, all SUV for each lesion were also lower than those on before therapy FDG scan, and the mean SUVs in cardiac and extra-cardiac lesions also decreased significantly ($p<0.001$ and $p<0.001$, respectively). The mean SUV reductions in cardiac and extra-cardiac lesions on FLT scan were 53% and 57%, respectively. The mean SUV reductions in cardiac and extra-cardiac lesions on FDG scan were 57% and 55%, respectively. No significant difference in SUV reduction was found between FLT and FDG scans.

CONCLUSION

This preliminary study indicates that FLT PET/CT, even without the usually necessary fasting, may have the potential to identify the therapeutic response in patients with cardiac sarcoidosis as well as FDG PET/CT.

CLINICAL RELEVANCE/APPLICATION

FLT PET/CT, even without the usually necessary fasting, may have the potential to identify the therapeutic response in patients with cardiac sarcoidosis.

SSA16-09 Feasibility of Using Global Lung FDG Uptake in COPD Patients on PET/CT to Assess the Correlation Between Pulmonary Parenchymal Inflammation and Pulmonary Function Test Indices as well as Emphysema Severity

pegah.jahangiri@uphs.upenn.edu

PURPOSE

The purpose of this study was to determine the relationship between the degree of pulmonary parenchymal inflammation measured from FDG-PET/CT with the degree of emphysema and also with PFT indices in chronic obstructive pulmonary disease (COPD) patients based on image segmentation and partial volume correction.

METHOD AND MATERIALS

56 COPD patients (51 men; median age 64) who underwent 18F-fluorodeoxyglucose-positron emission tomography/computed tomography (FDG-PET/CT) were studied. Lung parenchymal volume (L), macroscopic emphysema volume (E) and non-emphysematous lung parenchyma mean attenuation (A) were measured from CT images. Uncorrected maximum standardized uptake value of lung (USUVmax) was measured from PET/CT images. A first level of partial volume correction was then applied to account for varying amounts of macroscopic emphysema (CSUVmax) followed by a second level of correction to account for the mixture of air and lung parenchyma at the microscopic level (CCSUVmax). Correlation of fraction of emphysema(F=E/L) with USUVmax, CSUVmax, CCSUVmax were tested using Pearson correlation and linear regression statistical tests. Pearson correlation and linear regression statistical tests were applied to test the correlations of USUVmax, CSUVmax, and CCSUVmax with FEV1/FVC ratio.

RESULTS

Lung USUVmax and CSUVmax were not significantly correlated with fraction of emphysema ($r=0.03$, $p=0.831$ and $r=0.18$, $p=0.292$, respectively). However, CCSUVmax was significantly positively correlated with fraction of emphysema ($r=0.47$, $p=0.013$). Lung CSUVmax and CCSUVmax were significantly negatively correlated with FEV1/FVC ratio ($r=-0.49$, $p=0.026$ and $r=-0.71$, $p<0.001$, respectively), whereas there was no significant correlation between lung USUVmax and FEV1/FVC ratio ($r=-0.25$, $p=0.073$).

CONCLUSION

These data demonstrate that the degree of pulmonary inflammation increases with the degree of emphysema severity and that patients with lower FEV1/FVC ratios have greater degrees of pulmonary parenchymal inflammation based on FDG-PET/CT quantitative assessment. These correlations are more statistically significant when pulmonary FDG uptake is corrected for the partial volume effect, which shows the importance of partial volume correction for accurate quantification of lung disease severity.

CLINICAL RELEVANCE/APPLICATION

Measurement of pulmonary FDG uptake on PET/CT may therefore be useful in the diagnostic and response assessment of patients with COPD.

PURPOSE

The aim of this study was to test the hypothesis that high-resolution, T2-weighted magnetic resonance imaging (HRT2-MRI) is an acceptable alternative to gadolinium-enhanced T1-weighted MRI (Gd-MRI) in the assessment of size of vestibular schwannomas (VS). Current VS surveillance requires a minimum of 6 scans to demonstrate no interval growth. Proof of this hypothesis may allow a change in practice to performing VS surveillance imaging with HRT2-MRI rather than the current standard of T1-Gd MRI, a change that could have potential health and economic benefits; given the costs and potential complications from repeat gadolinium administration.

METHOD AND MATERIALS

Two neuroradiologists independently performed single dimension intra-canalicular measurements with, or without additional intra-cisternal measurements (depending on the tumour extension) on axial images of 50 VS imaged with HRT2-MRI and Gd-MRI. Paired student t-tests (alpha = 0.05) were used to determine whether differences in the mean tumour measurements between HRT2-MRI and Gd-MRI were statistically significant. Intraclass and interclass correlation coefficients (ICC) were calculated to determine intra- and interobserver reliability. Bland-Altman plots were used to evaluate the level of agreement between VS measurements obtained on HRT2-MRI and Gd-MRI.

RESULTS

There was no statistically significant difference in the mean diameter of VS size, measured on HRT2-MRI and Gd-MRI for both neuroradiologists ($p=0.28$ & $p=0.74$ for observer 1 and 2 respectively). Interobserver reliability between the neuroradiologists demonstrated excellent correlation for both imaging techniques (ICC=0.99 for HRT2-MRI and Gd-MRI). Intraobserver reliability was also excellent (ICC>=0.98 for both observers measuring on HRT2-MRI and Gd-MRI). Bland-Altman plots showed the differences between the two sequences were within limits of agreement for both observers.

CONCLUSION

This study supports the use of HRT2-MRI alone for the surveillance of known VS.

CLINICAL RELEVANCE/APPLICATION

High resolution T2 MRI shows good agreement with gadolinium-enhanced T1 MRI in measurement of vestibular schwannomas which could have health and economic benefits in their surveillance.

SSA17-02 Histogram Analysis of Diffusion Kurtosis Imaging for Differentiating Malignant from Benign Masses in Head and Neck Region

Sunday, Nov. 25 10:55AM - 11:05AM Room: E350

Participants
Hao Hu, Nanjing, China (*Presenter*) Nothing to Disclose
Gao Ma, Nanjing, China (*Abstract Co-Author*) Nothing to Disclose
Xiao-Quan Xu, Nanjing, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic performance of histogram parameters derived from diffusion kurtosis imaging (DKI) for differentiating malignant from benign masses in head and neck region.

METHOD AND MATERIALS

Our study retrospectively enrolled 80 patients with head and neck masses who had undergone DKI scan for pre-treatment evaluation. Patients were grouped into malignant group (n=64) and benign group (n=16). Apparent diffusion for Gaussian distribution (Dapp) and apparent kurtosis coefficient (Kapp) were generated. Histogram parameters, including mean, median, 10th, 90th percentiles, skewness and kurtosis of Dapp and Kapp were calculated. Independent-sample t test and Mann-Whitney U test were used to compare the differences of quantitative parameters between two study groups. Differentiating performances of significant parameters were determined by using receiver operating characteristic (ROC) curve analyses. Multivariable stepwise logistic regression was used to identify independent predictors of malignancy

RESULTS

Malignant group showed significantly lower Dapp-10th, Dapp-mean, Dapp-median and Dapp-90th, while higher Kapp-10th, Kapp-mean, Kapp-median and Kapp-90th than benign group (All Ps<0.001). Dapp-10th demonstrated significantly higher differentiating performance than Dapp-mean (P=0.039), while Kapp-90th also demonstrated significantly higher differentiating performance than Kapp-mean (P=0.008). Dapp-10th was the only independent predictor of malignancy, with a sensitivity of 0.813, and a specificity of 1.000 at a cut-off value of 0.989×10-3 mm2/s.

CONCLUSION

Histogram analysis of DKI holds promising for exhibiting the difference of tumor heterogeneity between malignant and benign head and neck masses. Dapp-10th may be the promising imaging biomarker for predicting malignant tumor in head and neck region.

CLINICAL RELEVANCE/APPLICATION

To assist in the differentiation of head and neck mass lesions.

SSA17-03 Texture Analysis of Diffusion-Weighted Imaging in Head and Neck Squamous Cell Carcinoma: Diagnostic Value for Nodal Metastasis

Sunday, Nov. 25 11:05AM - 11:15AM Room: E350

PURPOSE

To evaluate the diagnostic performance of texture features of diffusion-weighted imaging (DWI) in differentiating metastasis from benign lymph nodes (LNs) in head and neck squamous cell cancer (SCC).

METHOD AND MATERIALS

Between June, 2016 and February, 2018, thirty-six patients with pathologically proven head and neck SCC were included in this study. All patients underwent preoperative magnetic resonance imaging (MRI) including DWI and conventional imaging at 3T. Total 204 MRI-detected LNs including 176 subcentimeter normal-sized LNs were assigned to the metastatic or benign groups according to the pathology. Texture features including histogram and gray-level matrices were derived by drawing region-of-interest on LNs while excluding necrosis on apparent diffusion coefficient maps. Texture features between metastasis and benign LNs were compared using independent t-test, and hierarchical cluster analysis was performed to identify correlations between features. Multivariate logistic regression and receiver operating characteristic analysis were performed to assess diagnostic performance for metastatic LNs.

RESULTS

Total 83 out of 204 LNs in all-size were confirmed as metastasis; 58 out of 176 normal-sized LNs were metastasis. Three discriminative texture features for differentiating metastasis from benign LNs were complexity (all-size, P<.001, odds ratio [OR] 1.0000022, 95% confidence interval [CI] 1.000001-1.000004; normal-size, P=.001, OR, 1.000002, 95% CI, 1.0000008-1.000004), normalized energy (P=.014, OR 1.000002, 95% CI 1.0000004-1.000004; P=.001, OR 1.000002, 95% CI 1.0000009-1.000004) and roundness (P=.008, OR 103.56, 95% CI 3.35-3675.25; P=.008, OR 116.88, 95% CI 3.39-4675.74). Area under the curves (AUCs) for diagnosing metastasis in all-sized and normal-sized LNs were 0.829 and 0.767 regarding complexity, 0.699 and 0.685 regarding normalized energy, and 0.699 and 0.685 regarding roundness. The combination of three features resulted in higher AUC values of 0.836 and 0.781, respectively.

CONCLUSION

Texture analysis of DWI can be useful in diagnosing nodal metastasis in head and neck SCC, especially in normal -sized LNs.

CLINICAL RELEVANCE/APPLICATION

Texture analysis of diffusion-weighted imaging can be useful in differentiating benign and metastatic lymph nodes in head and neck squamous cell cancer.

SSA17-04 Treatment Response Assessment of Nasopharyngeal Carcinoma Based on Diffusion Kurtosis Imaging

Sunday, Nov. 25 11:15AM - 11:25AM Room: E350

Participants
Ning Tu, Wuhan, China (*Presenter*) Nothing to Disclose
Guangyao Wu SR, MD,PhD, Wuhan, China (*Abstract Co-Author*) Nothing to Disclose
Xiangyu Wang, Wuhan, China (*Abstract Co-Author*) Nothing to Disclose

tuning@whu.edu.cn

PURPOSE

The prediction of treatment response is important in planning and modifying the chemoradiation therapy regimen. This study aimed to explore the quantitative indices for treatment response assessment of nasopharyngeal carcinoma (NPC) based on diffusion kurtosis imaging(DKI).

METHOD AND MATERIALS

Thirty-six patients with initial diagnosis of locally advanced NPC and DKI acquisitions before and after neoadjuvant chemotherapy (NAC) were enrolled. Patients were divided into respond (RP) and non-respond (NRP) groups and residual (RD) and non-residual (NRD) groups after NAC and radiation therapy(RT). Histogram parameters (10th, 25th, 50th, 75th, 90th percentile, mean, standard deviation, skewness, and kurtosis) of DKI-derived parameters (ADC, D, K) were calculated. Intraclass correlation coefficient (ICC), Kolmogorov-Smirnov test, Student's t-test or Mann-Whitney U test, receiver operating characteristic curve (ROC) and Delong tests were performed.

RESULTS

Most of the parameters have good to excellent consistency (ICC: 0.675-0.998). The pre- and post-ADC (10th, 25th, 50th), D (10th, 25th, 50th) and K (50th) were significantly different between RP and NRP, while the pre- and post- ADC (10th, 50th), D (25th, 50th) and K (75th, 90th) were significantly different between RD and NRD (all $P<0.05$). ROC analysis indicated that setting pre-D50th=0.875mm2/s as the cut-off value could obtain optimal diagnostic performance for the prediction of NAC treatment response, while post-K90th=1.035 is optimal for prediction of RT response.

CONCLUSION

DKI derived parameters can be used as promising quantitative biomarkers in prediction of NAC and RT treatment response in locally advanced NPC patients.

CLINICAL RELEVANCE/APPLICATION

DKI derived parameters can be used as promising quantitative biomarkers in prediction of NAC and RT treatment response in locally advanced NPC patients.

SSA17-05 Differential Diagnosis of Nasopharyngeal Carcinoma and Nasopharyngeal Lymphoma Based on DCE-MRI and DWI

Sunday, Nov. 25 11:25AM - 11:35AM Room: E350

Participants
Chengru Song, Zhengzhou, China (*Presenter*) Nothing to Disclose
Jingliang Cheng, MD,PhD, Zhengzhou, China (*Abstract Co-Author*) Nothing to Disclose
Yong Zhang, DO, Zhengzhou, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the utility of dynamic contrast-enhanced MRI and diffusion weighted imaging (DWI) in the differentiation of nasopharyngeal carcinoma (NPC) and nasopharyngeal lymphoma (NPL).

METHOD AND MATERIALS

Fifty-two patients with pathologically confirmed NPC and 43 patients with NPL were recruited and underwent conventional MRI and dynamic contrast-enhanced MRI. The MR signals, time signal-intensity curves(TIC) types, time to peak(TTP), enhancement peak(EP), maximum contrast enhancement ratio(MCER), washout ratio(WR), ADC and relative ADC value of all the subjects were calculated and analyzed, thereafter, inter-group comparison was performed. The threshold values of TTP, EP, MCER, WR, ADC and rADC for differentiating NPC from NPL were determined using a receiver operating characteristic curve (ROC) analysis.

RESULTS

For NPC group, 40 cases (76.19%) demonstrated obvious heterogeneous enhancement. The mean TTP, EP, MCER and WR were (48.29±12.20)s, 1475.38±77.76, (136.89±24.41)% and 16.81±8.36, respectively. For NPL group, 38 cases (88.89%) demonstrated obvious homogeneous enhancement. The mean TTP, EP, MCER and WR were (63.21±14.29)s, 1161.82±64.04, (113.47±28.52)% and 7.39±6.21, respectively. The ADC value and rADC value were (842.34±94.66)×10-6 mm2·s-1 and 0.74±0.08 in NPC, whereas (652.15±83.47)×10-6 mm2·s-1 and 0.56±0.08 in NPL. The differences of TTP, EP, MCER, WR, ADC, rADC between NPC and NPL were statistically significant ($P<0.05$). The TTP of NPC was lower than that of NPL, whereas the opposite for the remaining parameters. ADC and rADC value reveled the highest diagnostic efficiency in differentiating NPC from NPL, while rADC was even slightly superior to ADC. The best differentiate threshold value of ADC and rADC were 736.5×10-6mm2·s-1, 634.0×10-6mm2·s-1, respectively. While the areas under the ROC curve (AUC), sensitivity, specificity and Youden index of ADC and rADC were 0.943, 0.909, 0.852, 0.761, and 0.951, 0.955, 0.852, 0.77, respectively.

CONCLUSION

Dynamic contrast-enhanced MRI and DWI are effective in differentiating NPC from NPL. ADC and rADC value reveled the highest diagnostic efficiency.

CLINICAL RELEVANCE/APPLICATION

Dynamic contrast-enhanced MRI and DWI can be applied in the differential diagnosis of NPC from NPL.

SSA17-06 Deep Learning-Based Computer-Aided Diagnosis System for Diagnosis of Cervical Lymph Node Metastasis from Thyroid Cancer on Computed Tomography: A Pilot Study

Sunday, Nov. 25 11:35AM - 11:45AM Room: E350

Participants
Eun Ju Ha, Suwon, Korea, Republic Of (*Presenter*) Nothing to Disclose
Jeong Hoon Lee, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Surgical extent of thyroid cancer relies on the accurate preoperative detection of lymph node metastasis. Therefore, contrast-enhanced computed tomography (CT) is recommended as an adjunct to ultrasonography for patients with clinical suspicion for advanced disease. The purpose of this study was to develop the computer-aided diagnosis (CAD) system to differentiate metastatic lymph nodes on preoperative CT.

METHOD AND MATERIALS

From May 2013 to July 2017, we enrolled 995 lymph nodes seen on CT, which were confirmed by fine-needle aspiration or surgery. The datasets were split into training (543 benign and 244 metastatic lymph nodes), validation (52 benign and 52 metastatic lymph nodes), and test (52 benign and 52 metastatic lymph nodes). Using the GoogLeNet-Class Activation Map model, we developed a CAD system to differentiate the metastatic lymph nodes. We evaluated the diagnostic performance of this CAD system in our test set.

RESULTS

In the test set, the sensitivity, specificity, and accuracy of our model for predicting cervical lymph node metastasis were 84.62%, 96.15%, and 90.38%, respectively. The area under the receiver operating characteristic curve was 0.912 for the CAD system.

CONCLUSION

We developed a deep learning-based CAD system for differentiation of lymph nodes metastasis from thyroid cancer on preoperative CT. This CAD system is highly accurate and may be used as an adjunctive tool for preoperative diagnosis of lymph node metastasis.

CLINICAL RELEVANCE/APPLICATION

This study is an initial report to develop a deep learning-based CAD system for diagnosis of metastatic cervical lymph nodes on preoperative CT.

SSA17-07 Therapy Effects of Advanced Laryngeal Squamous Cell Carcinoma: Evaluated Using MTRasym3.5ppm in Magnetic Resonance Amide Proton Transfer Images

Sunday, Nov. 25 11:45AM - 11:55AM Room: E350

Participants
Xiaojie Luo, MD, Beijing, China (*Presenter*) Nothing to Disclose
Lu Yu, BS, Beijing, China (*Abstract Co-Author*) Nothing to Disclose
Min Chen, MD, PhD, Beijing, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

The accurate evaluation of the therapeutic effects of advanced laryngeal squamous cell carcinoma (LSCC) remains challenging. In this study, we determined the value of MTRasym3.5ppm derived from amide proton transfer weighted for predicting the therapeutic effects of advanced LSCC and to provide valuable evidence for early judgement of the tumour's response to therapy in clinical practice.

METHOD AND MATERIALS

We prospectively analysed 41 patients with pathologically confirmed LSCC. All patients were underwent MRI on the neck before therapy. Amide Proton Transfer (APT) images (saturation time 0.8 s, saturation power 2 μT) was performed under 3.0 Tesla MR scanner. APT images were calculated using magnetization transfer ratio asymmetry at 3.5ppm with respect to water. 19 of 41 patients showed complete remission (CR), and 22 showed non-complete remission (NCR).

RESULTS

The mean of MTRasym3.5ppm in the CR group were significantly lower than the NCR group ($P<0.05$). There were no significant differences for T stage, treatment modality between two groups ($P>0.05$). The 2-year cumulative recurrence rate of patients with higher MTRasym3.5ppm values was significantly higher than that of patients with lower MTRasym3.5ppm values ($P<0.05$), while the 2-year survival rate of those patients was not significantly different ($P>0.05$).

CONCLUSION

APT could easily identify CR patients and potentially help to choose the appropriate treatment regimen for advanced LSCC.

CLINICAL RELEVANCE/APPLICATION

MTRasym3.5ppm derived from amide proton transfer weighted for predicting the therapeutic effects of advanced LSCC

SSA17-08 Computer-Aided Diagnosis System for Thyroid Nodules Seen on Ultrasonography: Diagnostic Performance and Reproducibility Based on Operator Experience

Sunday, Nov. 25 11:55AM - 12:05PM Room: E350

radhej@naver.com

PURPOSE

To evaluate the diagnostic performance and reproducibility of a computer-aided diagnosis (CAD) system for thyroid cancer diagnosis using ultrasonography (US) based on the operator's experience

METHOD AND MATERIALS

Between July 2016 and October 2016, 76 consecutive patients with 100 thyroid nodules (>= 1.0 cm) were prospectively included. An experienced radiologist performed the US examinations with a real-time CAD system integrated into the US machine, and three operators with different levels of US experience (0-5 years) independently applied the CAD system. We compared the diagnostic performance of the CAD system based on the operators' experience and calculated the interobserver agreement for cancer diagnosis and in terms of each US descriptor.

RESULTS

The sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of the CAD system were 88.6, 83.9, 81.3, 90.4, and 86.0%, respectively. The sensitivity and accuracy of the CAD system were not significantly different from those of the radiologist ($P > 0.05$); while the specificity was higher for the experienced radiologist ($P = 0.016$). For the less-experienced operators, the sensitivity was 68.8-73.8%, specificity 74.1-88.5%, PPV 68.9-73.3%, NPV 72.7-80.0%, and accuracy 71.0-75.0%. The less-experienced operators showed lower sensitivity and accuracy than those for the experienced radiologist (all $P<0.05$). The interobserver agreement was good for the final diagnosis and each US descriptor; however, the margin and composition remained moderate agreement.

CONCLUSION

The CAD system may have a potential role in the thyroid cancer diagnosis. However, operator dependency still remains and needs improvement.

CLINICAL RELEVANCE/APPLICATION

1. The sensitivity and accuracy of the CAD system did not differ significantly from those of the experienced radiologist (88.6% vs. 84.1%, P=0.687; 86.0% vs. 91.0%, P=0.267) while the specificity was significantly higher for the experienced radiologist (83.9% vs. 96.4%, P=0.016). 2. However, the diagnostic performance varied according to the operator's experience (sensitivity 70.5-88.6%, accuracy 72.0-86.0%) and they were significantly lower for the less-experienced operators than for the experienced radiologist (all $P<0.05$). 3. The interobserver agreement was good for the final diagnosis and each US descriptor; however, the margin and composition remained moderate agreement.

SSA17-09 Detection of Parathyroid Adenomas with Wide-Beam Multiphase CT: Towards a True Four-Dimensional Visualization Technique with Quantitative Analysis of Perfusion Parameters

Sunday, Nov. 25 12:05PM - 12:15PM Room: E350

Steven.Raeymaeckers@uzbrussel.be

PURPOSE

Diagnosis of a parathyroid adenoma on CT is typically based upon features obtained from three consecutive phases: Low attenuation (NECT) Arterial peak enhancement Rapid washout of contrast in venous phase However, if timing of these phases is not optimal, wash-in or wash-out phenomena can appear less conspicuous or could even be missed. In this ethical compliant study we explore the possibility of using a multiphase (16x) technique in continuous axial scanning mode in order to perform quantitative perfusion analysis.

METHOD AND MATERIALS

Up to date, we included 13 patients with suspected primary hyperparathyroidism (i.e. an elevated serumlevel of calcium and raised levels of parathyroid hormone) prior to surgery. Continuous axial scanning (Revolution CT, GE Healthcare) was performed over a fixed 8 cm volume (100 kVp, 0.625 mm) with following temporal scan protocol: Non-contrast scan Contrast administration (90 mL, 6 mL/s) followed by 20 sec delay 11 phases with a 2-second interphase delay 4 phases with a 10-second interphase delay The following perfusion parameters were considered in the normal thyroid, parathyroid and lymph nodes: maximum peak enhancement (HUmax), mean blood flow (MBF) and volume (MBV), time to peak (TTP) and mean slope of increase (MSI).

RESULTS

In all but 2 patients the enlarged parathyroid can be visualized. Parathyroid adenomas show a different enhancement pattern compared to the thyroid, with an obvious wash-in of contrast. Most adenomas show an obvious wash-out of contrast. Normal cervical lymph nodes show a continuous and shallow increase of enhancement. HUmax of visualised adenomas is well above the normal thyroid gland (mean 474 vs 332 HU). MBF in the adenoma is 93% higher compared to the thyroid (mean 507,5 vs 263 mL/100g/min). Similarly MBV is increased with 69% (mean 21.6 vs 12.8 mL/100g). Adenomas demonstrate earlier peak enhancement, at 29.6s versus 31.6s for the thyroid. MSI is significantly steeper for the adenomas compared with normal thyroid tissue. Mean dose length product was 530±238 mGycm

CONCLUSION

Quantitative analysis of perfusion parameters obtained by multiphase CT can be used for detection and differentiation of parathyroid adenomas.

CLINICAL RELEVANCE/APPLICATION

Improved detection and differentiation of parathyroid adenomas is a key factor in the diagnosis and treatment of primary hyperparathyroidism.

daniel.eftekhari@mail.utoronto.ca

PURPOSE

Multiple sclerosis (MS) and cerebral small vessel disease (SVD) may be difficult to distinguish using only neuroimaging and clinical presentation. As early diagnosis and treatment is associated with better long-term outcome in both diseases, and the societal and monetary cost for both diseases is potentially high, particularly for misdiagnosis in MS, we developed an accurate and automatic diagnostic algorithm to differentiate relapsing-remitting MS (RRMS) and SVD using neuroimaging and clinical presentation.

METHOD AND MATERIALS

Statistical and machine learning algorithms, including a mixture of *t*-distributions and a novel spatial heuristic algorithm, were developed for the segmentation of white matter hyperintensities and T1 black holes on FLAIR and T1 W MRI sequences. Combined spatial probability maps of RRMS and SVD lesion masks were subsequently developed using a derivation set of patients. A novel cross entropy image distance metric, which is insensitive to co-registration and anatomical differences between patients, was used to quantify the similarity of new cases to each disease. Bayesian learning algorithms using non-informative priors were trained using these neuroimaging features in combination with clinical presentation. Model hyperparameters were tuned using Monte Carlo cross validation.

RESULTS

The dataset consists of 39 RRMS (median age 48 (31 - 60), 12 M, 27 F) and 72 SVD patients (median age 73 (52 - 86), 44 M, 28 F). An intraclass correlation coefficient (two-way random effects, absolute agreement, single measures) of 0.952 (95% CI [0.902, 0.976]) between total lesion volume for the automatic segmentations and RRMS ground truth tracings was obtained. The segmentation algorithms provide the additional benefit of being blind to disease ground truth, and are robust to varying MRI acquisition parameters. The model consisting of both neuroimaging and clinical features achieved 95% sensitivity and 99% specificity in distinguishing RRMS from SVD. This was a significant improvement on models developed using neuroimaging and clinical presentation in isolation.

CONCLUSION

Future directions include using additional predictors thought to distinguish the diseases in the predictive models, and extending the model to multi-disease classification.

CLINICAL RELEVANCE/APPLICATION

As the misdiagnosis rate for MS is 5-10%, and the societal and monetary cost of both diseases is high, this work has real potential for clinical impact.

SSA18-02 Diffusion Basis Spectrum Imaging (DBSI) Quantitatively Assesses Axonal Protection of FTY720 in Mice with Optic Neuritis

Sunday, Nov. 25 10:55AM - 11:05AM Room: E352

yangrm0708@gmail.com

PURPOSE

Diffusion basis spectrum imaging (DBSI) has been introduced to overcome the limitations of diffusion tensor imaging (DTI) to accurately detect and distinguish confounding neuropathologies in MS[1, 2, 3]. Optic neuritis is frequently the first symptom of MS. Fingolimod (FTY720) was the first FDA-approved oral agent for treating MS[4]. Although its anti-inflammatory effect is clear, neuroprotection, which is highly associated with neurological function, remains uncertain. This study investigates whether FTY720 treatment protects optic nerve axons from EAE mice with optic neuritis using in vivo DBSI.

METHOD AND MATERIALS

EAE was induced in C57BL/6 mice as previously reported. Daily clinical score and visual acuity (VA) were assessed. When VA <= 0.25 cycle/degree, mice were alternately assigned to receive daily gavage of either FTY720 (1 mg/kg bw) or the same amount of saline for 10 consecutive weeks. MRI experiments were performed on a 4.7 T small-animal scanner. For each EAE mouse, baseline DBSI was performed two weeks prior to immunization with follow-up scans at 2, 6 and 10 weeks post-treatment. The 25-direction diffusion-weighted imaging acquisition was performed with TR = 1500 ms, TE = 35 ms, NE = 2, FOV = 22.5 × 22.5 mm2, matrix size = 192 × 192, slice thickness = 0.8 mm, max. b value = 2,200 s/mm2, Δ = 18 ms, δ = 6 ms. The total scan time = 2 hr 4 min. Mice were perfusion fixed immediately after final in vivo DBSI for immunohistochemical assessment of axonal injury/loss, demyelination and cellular inflammation.

RESULTS

Compared with saline-treated group, FTY720 treatment slowed VA deterioration and protected against inflammation, demyelination, and axonal injury/loss as seen by in vivo DBSI-derived neuroimaging biomarkers, validated by post-DBSI immunohistochemical analysis.

CONCLUSION

Current results suggest that FTY720 reduce axonal loss in EAE mouse optic nerve. This may be direct or indirect based on its anti-inflammatory effects. We propose that DBSI could serve as a non-invasive biomarker to monitor disease progress and validate treatment efficacy for MS patients.

CLINICAL RELEVANCE/APPLICATION

Results support that DBSI derived pathological metrics can be used to assess the therapeutic efficacy of disease modifying therapies in MS and potentially other diseases.

SSA18-03 Whole Brain Adiabatic T1rho and Relaxation Along a Fictitious Field Imaging in Healthy Volunteers and Patients with Multiple Sclerosis: Initial Findings

PURPOSE

To evaluate feasibility of whole brain adiabatic T1ρ and Relaxation Along a Fictitious Field (RAFF) imaging in healthy volunteers and patients with multiple sclerosis (MS).

METHOD AND MATERIALS

Twenty-eight healthy volunteers (24 - 69 years) and nine patients (35- 45 years) with relapsing-remitting MS provided written informed consent and underwent MRI examination performed using a clinical 3 Tesla MR scanner as a part of an ongoing single institutional clinical trial. Relaxation Along a Fictitious Field in second rotating frame of reference (RAFF2) was performed using RF peak amplitude of 11.74 μT and pulse train durations of 0, 45, 90 ms. The adiabatic T1ρ data sets were obtained using hyperbolic secant (HS) pulses with the RF peak amplitude of 13.50 μT and pulse train duration of 0, 72ms, and 144 ms. The parametric maps of TRAFF and T1ρ were calculated using two parameter monoexponential model. Semi-automatic segmentation of MS lesions, white matter (WM), and gray matter (GM) was performed based on T1 and FLAIR weighted images. Mean TRAFF and T1ρ in normal-appearing WM, GM, and lesions were compared within and between subject groups by using analysis of variance.

RESULTS

The number of healthy volunteers in 20-29, 30-39, 40-49, 50-59, 60-69 age groups was 7, 5, 6, 6, 4, respectively. The differences in the median relaxation values between the age groups did not reach the level of statistical significance. Similarly, Pearson correlation coefficients were not statistically significant for any of the relaxation parameters. In contrast, statistically significant differences in TRAFF and T1ρ values were present between the tissue types in MS patients.

CONCLUSION

Statistically significant differences were present in TRAFF and T1ρ values between normal-appearing WM, GM, and lesions in patients with MS. Theses encouraging preliminary results support further instigation of RAFF for the evaluation of MS.

CLINICAL RELEVANCE/APPLICATION

Relaxation Along a Fictitious Field (RAFF) is a novel promising imaging method for evaluation of patients with multiple sclerosis.

SSA18-04 MRI Findings in Tumefactive Demyelinating Lesions: A Systematic Review and Meta-Analysis

Sunday, Nov. 25 11:15AM - 11:25AM Room: E352

Participants
Chan Park, Gwangju, Korea, Republic Of (*Presenter*) Nothing to Disclose
Chong Hyun Suh, MD, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Ho Sung Kim, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

We aimed to evaluate conventional and advanced MRI findings for the diagnosis of tumefactive demyelinating lesions (TDL) and determine the diagnostic performance of MRI for differentiating TDL from primary brain tumor.

METHOD AND MATERIALS

A systematic search of Ovid-MEDLINE and EMBASE up to December 6, 2017, was conducted to find relevant studies. The pooled incidence of conventional MRI TDL findings was obtained with the inverse variance method for calculating weights and the DerSimonian-Liard random-effects model. Pooled sensitivity and specificity were obtained using a bivariate random-effects model.

RESULTS

Eighteen eligible studies with 325 TDL patients were included. The pooled incidence of open ring or incomplete rim enhancement was 36% (95% CI, 25-47%), which was significantly higher than the incidence of closed ring or complete rim enhancement (13% [95% CI, 6-21%]; p = 0.0013). The pooled incidences of T2 hypointense rim, absent or mild mass effect, and absent or mild perilesional edema were 46% (95% CI, 25-68%), 64% (95% CI, 42-87%), and 55% (95% CI, 27-82%), respectively. Open ring or incomplete rim enhancement showed high specificity (98-100%). On advanced MRI, TDL showed a high apparent diffusion coefficient, peripheral restricted diffusion, and low cerebral blood volume. The pooled sensitivity and specificity of MRI for differentiating TDL from primary brain tumor were 89% (95% CI, 82-93%) and 94% (95% CI, 89-97%), respectively.

CONCLUSION

Conventional MRI findings may help differentiate TDL from primary brain tumor, although further study is needed to determine the added value of advanced MRI.

CLINICAL RELEVANCE/APPLICATION

Conventional MRI findings may help differentiate TDL from primary brain tumor.

SSA18-05 In-Vivo Tissue Marker of Neuro-Inflammation is Associated with WMH Burden: A Multimodal PET-MR stu

Sunday, Nov. 25 11:25AM - 11:35AM Room: E352

PURPOSE

White matter hyperintensities (WMH) on FLAIR have been widely observed in patients with cerebral small vessel disease (CSVD) and Alzheimer's disease (AD). WMH is strongly associated with progression to dementia. The pathogenesis of WMH is poorly understood. Animal models and post-mortem human brain studies have suggested a role of neuro-inflammation in WMH. However, there is no in vivo data from patients to provide direct evidence. In addition, it is unclear whether amyloid deposition, a hallmark pathological feature of AD, may be directly linked to WMH. In this study, we evaluated whether neuroinflammation and amyloid deposition are associated with WMH burden using PET-MR imaging.

METHOD AND MATERIALS

18 elderly subjects (11 females, age: 76 [69, 82] (Median [interquartile range IQR])) underwent serial PET and MR scans. 11C-PK11195 PET images were acquired to estimate neuroinflammation. In addition, 11C-PiB PET to measure amyloid deposition, were acquired 19 [14, 22] (Median [IQR]) months prior to the 11C-PK11195 scans from the same patients. WMH lesions were manually outlined using FLAIR images to obtain WMH volumes (VWMH). MR T1w MPRage images were used for brain tissue segmentation. Standardized uptake value ratio (SUVR) maps were obtained using cerebellum gray matter as a reference. Linear regression was performed between VWMH vs. 11C-PK11195 SUVR in WM and GM, VWMH vs. 11C-PiB uptake, and VWMH vs. age, respectively.

RESULTS

VWMH across the elderly cohort was 8.4 ml [4.6ml 24.5ml]. 5 patients had a clinical dementia rating (CDR) score greater than 0.5 (CDR=0.5, n=3, CDR=1, n=2). 11C-PK11195 SUVR within WM, but not GM, was linearly associated with VWMH (R=0.54, P=0.022), suggestive of WM neuro-inflammation (Figure). Interestingly, amyloid deposition was not associated with VWMH (R=0.11, P=0.67).

As expected, age was linearly associated with VWMH (R=0.51, P=0.029).

CONCLUSION

Our results demonstrate that selective WM 11C-PK11195 uptake is associated with WMH burden, suggesting neuro-inflammation as a mechanism underlying CSVD and vascular cognitive impairment. In contrast, amyloid deposition is not associated with WMH.

CLINICAL RELEVANCE/APPLICATION

Selectively elevated PET 11C-PK11195 uptake within white matter demonstrates that neuro-inflammation is an important pathogenic factor in patients with white matter hyperintensity.

SSA18-06 Automated Brain Volumetry of Neuromyelitis Optica Spectrum Disorders: Inter-Scanner Variability in White Matter Hyperintensities Segmentations, and Volumetric Differences Compared with Multiple Sclerosis

Sunday, Nov. 25 11:35AM - 11:45AM Room: E352

guochunjie@hotmail.com

PURPOSE

To verify AccuBrain is a robust software for white matter lesions (WMLs) and brain volumetric segmentation in neuromyelitis optica spectrum disorders (NMOSD), and to distinguish NMOSD from multiple sclerosis (MS) in neuroimaging.

METHOD AND MATERIALS

30 NMOSD and 30 MS patients well matched on age and gender from 3D images protocol at the same scanner were recruited in the first study on evaluating brain volumetric and WML differences. In addition, 6 of the NMOSD subjects agreed to enroll in a prospective study on inter-scanner variability and were scanned at 5 different scanners within 24 hours. 2D FLAIR images were obtained from all the sites, while one 3T scanner was also used to acquire 3D T1W and FLAIR images Two automated segmentation software, AccuBrain and lesion segmentation tool (LST) toolbox for SPM were used in WMLs segmentation to assess inter-scanner repeatability. To evaluate the volumetric and WML differences between NMOSD and MS, AccuBrain was used to perform automated segmentation and quantification of WML volumes, regional brain volumes and atrophy. Coefficient of variation (CV) was calculated to assess the effect of scanners on the variability in lesion segmentation, and two-sample t test was used to evaluate the differences of each regional volumetric measure between NMOSD and MS.

RESULTS

The mean inter-scanner CV of WML volume is 14.6% ± 8.4% when using AccuBrain, which is smaller compared to that of 23.6% ± 11.2% when using LST. In the brain volumetric analysis from 3D T1WI, although NMOSD and MS generally presented similar brain atrophy pattern, we found that they differ significantly in the thalamus-proper, lateral ventricle and third ventricle. In the WML analysis from 3D FLAIR images, significant volume difference was found between NMOSD and MS in white matter hyperintensities, which can be illustrated in the WML prevalence maps from the voxel-based lesion-symptom mapping (VLSM) analysis, with MS group having more WMLs situated over the posterior horns of the lateral ventricles.

CONCLUSION

AccuBrain is a robust software for calculating WMLs in NMOSD patients in multicenter and longitudinal studies. In addition, NMOSD differs from MS not only in brain atrophy pattern, but also in WML volume and location, and AccuBrain is a suitable software for analysis.

CLINICAL RELEVANCE/APPLICATION

AccuBrain is a robust software for calculating WMLs and brain volumetric segmentation in NMOSD and MS patients.

SSA18-07 Diagnostic Accuracy of the Post-Contrast Double Inversion Recovery (DIR) T2 Sequence and Its Double Inversion Time Influence on the Multiple Sclerosis (SM) Plaque Signal

PURPOSE

To assess the diagnostic accuracy of the DIR T2 sequence in recognizing relapsing or clinically suspicious active MS plaques by using the influence of double inversion time on the scan signal obtained after administered paramagnetic MDC.

METHOD AND MATERIALS

A total of Forty patients with clinically classified MS disease underwent brain magnetic resonance examinations. All the exams were performed using MR 3T scanner, with standard protocol and use of magnetic susceptibility weighted image sequences (SWI) with subsequent acquisition of Magnetization Prepared Rapid Gradient-Echo (MPRAGE T1) and pre and post-contrast DIR sequences. Two neuroradiologists, blinded on the degree of the clinical status of the disease, evaluated with final consent all the images to identify the presence or absence of lesion enhancements.

RESULTS

Fourteen out of 40 patients did not show active plaques in the post-contrastographic sequences during remission; SWI only confirmed the presence of iron deposition as a biomarker of the disease. A total of 35 enhanced lesions were detected in 26 patients. The MPRAGE T1 sequences detected 29 lesions (82.8% of the total) in 22 patients; all these lesions showed a reduction in the signal in the post-contrastographic DIR sequences, while the same sequence after MDC showed 6 (17.2%) new cortical lesions active with signal increase in the remaining 4 patients.

CONCLUSION

Our results demonstrate that the DIR post-contrast sequence has a higher diagnostic accuracy than post-contrast T1-weighted sequences in detecting different degrees of inflammation of MS plaques.

CLINICAL RELEVANCE/APPLICATION

The Double Inversion Time of DIR sequence is able to visualize different active degree of MS plaques. We believe this MRI findings can detect minimal relapse or remission of the disease and can be a useful tool for evaluate treatment response.

SSA18-08 Two-Tiered MRI Workup to Rule Out Multiple Sclerosis (MS) Based on Specialty of Referring Physician

Sunday, Nov. 25 11:55AM - 12:05PM Room: E352

Participants
Khashayar Rafatzand, MD, Worcester, MA (*Presenter*) Nothing to Disclose
Farshad Safaei, Montreal, QC (*Abstract Co-Author*) Nothing to Disclose

khashayar.rafatzand@umassmemorial.org

PURPOSE

To determine cost-effectiveness of a two-tiered MRI protocol for MS based on specific referral patterns.

METHOD AND MATERIALS

Data was extracted from PACS & RIS in a community hospital July 2011-August 2017. INCLUSION: 1. Patients referred for MRI of brain. 2. 'rule-out MS'; EXCLUSION: 1. Previous/known MS, 2. Prior abnormal MRI. MRI protocols: screening (MRIScrC-=Ax FLAIR, Sag Proton-density, Sag T2) vs diagnostic (MRIDxC+=Sag T1 Ax T2, Ax FLAIR, Ax T2*, Ax DWI, Ax T1 pre-contrast, Ax T1 post-contrast, Sag 3D T1 post-contrast) MRI results: 1. Negative = Normal or not suspicious for demyelination. 2. Positive = Suspicious for demyelinating disease: call back required for the traditional MRI. Technical MRI parameters: 1. Sequence list 2. Allocated MRI time 3. Presence or absence of contrast Referring MD info 1. Neurologist vs. Non-neurologist Patient demographics: 1. Age, Gender, Disposition (Outpatient, ER, Inpatient) Resources & costs identified: MRI operations cost (including scan time, room time, technologist time, secretary time), Radiologist professional fees, contrast cost (IV equipment & MRI contrast), Renal function testing for MRIDxC+, patient visit (parking). Three scenarios were simulated: A) All patients undergo MRIDxC+ (similar to most regional practices). B) All patients underwent MRIScrC-. Patients with positive results called back for MRIDxC+. C) Patients referred by neurologist followed pathway B, patients referred by non-neurologists followed pathway A.

RESULTS

343 patients were included. (Table 1). MRI results were positive in 9/52 (%17.3) of neurologists' and 31/291 (%10.6) of non-neurologists' patients (p= 0.029). MRI exam time: MRIScrC- 20-minutes, MRIDxC+ 35-minutes. Costs: MRI operations ($65.6/hour), radiologist fees ($105/case), contrast ($17.17), Renal testing ($41.28), patient visit ($20/visit). MRI cost in each scenarios: A) $241.95, B)$161.47 (%66.7 of A) , C) $175.7 (%72.6 of A). Total savings in B and C: $27604.64, $22723.75.

CONCLUSION

We have demonstrated a higher pre-test probablity for abnormal MRI results based on referring physician's speciality (neurologists in case of MS). A two-tiered MRI protocoling system based on referral source has not been described, and in this population & practice led to significant cost-savings.

CLINICAL RELEVANCE/APPLICATION

Referral patterns should be considered in application of targeted MRI workup strategies.

SSA18-09 Iron Deposition and Thickness Changes in the Optic Radiation in Relapsing-Remitting Multiple Sclerosis: An Enhanced T2*-Weighted Angiography Imaging Study

Sunday, Nov. 25 12:05PM - 12:15PM Room: E352

Participants
Chun Zeng, Chongqing, China (*Presenter*) Nothing to Disclose
Yongmei Li, Chongqing, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

This study was aimed to investigate iron deposition and thickness and signal changes in optic radiation (OR) in patients with

This study was aimed to investigate iron deposition and thickness and signal changes in optic radiation (OR) in patients with relapsing-remitting multiple sclerosis (RRMS) by enhanced T2*-weighted angiography imaging (ESWAN).

METHOD AND MATERIALS

Fifty-one RRMS patients (42 patients with a disease duration [DD] >= 2 years [group Mor], 9 patients with a DD < 2 years [group Les]) and 51 healthy controls (group Con) underwent conventional MRI and ESWAN at 3.0 T. Mean phase value (MPV) of the OR was measured on the phase image, and thickness and signal changes were observed on the magnitude image.

RESULTS

Group Mor had the lowest MPV. In group Mor, 28 patients with bilateral OR lesions showed bilateral OR thinning with a heterogeneous signal, 14 patients with unilateral OR lesions showed ipsilateral OR thinning with a heterogeneous signal. In the remaining nine patients without OR lesions, bilateral OR showed a normal appearance. In the patients, a negative correlation was found between DD and OR thickness and a positive correlation was found between MPV and OR thickness.

CONCLUSION

We confirmed iron deposition in the OR in RRMS patients, and the OR thickness was lower in the patients than in the controls.

CLINICAL RELEVANCE/APPLICATION

3D-ESWAN can detect iron deposition in the OR in RRMS patients from the early stage of the disease, and the thickness of the OR in patients with a longer DD is lower than that in the controls. Thus, iron deposition in the OR is more pronounced in the early stage and occurs independent of its morphology.

manzae.kim@gmail.com

PURPOSE

The purpose of this study was to determine whether quantitative measurement of tau deposition from [18F]THK-5351 positron emission computed tomography (Tau PET) can improve diagnosis of Alzheimer's disease spectrum with well-defined structural volumetry on MRI.

METHOD AND MATERIALS

From a prospective database in a multicenter study (NCT02656498), 113 subjects who had both baseline structural MRI and Tau PET within 6 month interval were included. There were 32 normal controls (NC), 55 mild cognitive impairment (MCI), and 26 Alzheimer's disease (AD) patients, and all institutions received IRB approval. Hippocampal volume was quantified from FDA-approved software for automated volumetric MRI analysis (Neuroquant) using T1-weighted-images. Standardized uptake value ratio (SUVr) was calculated from Tau PET images for 6 composite FreeSurfer-derived regions-of-interests (ROIs) approximating the anatomical definitions of in-vivo Braak stage 6 regions (Braak ROIs). Analysis of variance was performed to determine locations for structural volumetry analysis. Diagnostic performance of Tau PET ROIs and structural volumetry were compared using the area under the receiver-operating characteristic curve (AUROC).

RESULTS

Compared with NC, MCI and AD showed significantly lower hippocampal volume (mean±standard deviation, NC, 7.14±0.84; MCI, 5.99±1.18; AD, 5.90±1.30mm3, P=0.01) and AD showed lower anterior cingulate volume (NC, 6.09±0.85; MCI, 6.00±0.76; AD, 5.43±0.91mm3, P=0.006). The diagnostic performance of structural volumetry (hippocampus and anterior cingulate) was higher than Braak ROIs in diagnosing AD from MCI (volumetry AUROC 0.70, 0.57-0.83 vs. Tau PET AUROC, 0.60, 0.48-0.71) or in diagnosing AD from NC (volumetry AUROC 0.84, 0.73-0.94 vs. Tau PET AUROC, 0.78, 0.65-0.87). Adding Braak ROIs significantly improved diagnostic performance in distinguishing AD from MCI (AUROC 0.81, 0.70-0.92, P<0.01) as well as AD from NC (AUROC, 0.93, 0.87-0.99, P <0.05) than using structural volumetry or Tau PET alone.

CONCLUSION

Quantitative analysis of tau deposition improved the diagnostic performance compared to structural volumetry alone in diagnosis of Alzheimer's disease spectrum, especially in diagnosis of Alzheimer's disease.

CLINICAL RELEVANCE/APPLICATION

Differentiating AD from MCI still remains as a diagnostic challenge in clinical practice and adding quantitative Tau deposition using Braak ROIs may become a potentially useful imaging biomarker.

SSA19-02 White Matter Cellularity Change Correlates with CSF ß-Amyloid in Preclinical Alzheimer's Disease

Sunday, Nov. 25 10:55AM - 11:05AM Room: E351

Participants

Qing Wang, PhD, St. Louis, MO (*Presenter*) Nothing to Disclose
Suzanne Schindler, St Louis, MO (*Abstract Co-Author*) Nothing to Disclose

Tammie S. Benzinger, MD,PhD, Saint Louis, MO (*Abstract Co-Author*) Research Grant, Eli Lilly and Company Investigator, Eli Lilly and Company Investigator, F. Hoffmann-La Roche Ltd

PURPOSE

Innate immune cells, particularly microglia and astrocytes, have been reported to mediate the inflammatory response in Alzheimer disease (AD) and are considered to be an important contributor to AD pathogenesis. In the AD brain, Aß deposition and neurofibrillary tangles provide obvious stimuli for neuroinflammation. This study aims to investigate the relationship between CSF ß-amyloid (Aß42) (a marker of Aß deposition) and white matter cellularity change (reflecting immune cell activation) in preclinical AD using a diffusion MRI based method, neuro-inflammation imaging (NII).

METHOD AND MATERIALS

CSF samples from 143 participants (average age 65.0 ± 8.2) with normal cognition underwent analysis for Aß42, total tau (tTau) and phosphotau 181 (pTau) with Roche Elecsys assays performed on the automated Roche cobas e 601 analyzer. NII was acquired with multi-b value scheme (bmax =1400s/mm2 and 23 directions). NII cell diffusivity (reflecting inflammatory cell activation) and cell fraction (reflecting inflammatory cell infiltration) was quantified by solving the NII model. The whole brain voxel-wise DTI-indices was analyzed using Tract Based Spatial Statistics (TBSS) (available in FSL).

RESULTS

NII cell diffusivity and cell fraction in major WM tracts was negatively correlated with CSF levels of Aß42 (Fig. 1 and 2). As an estimate of effect size, partial correlations were also examined between the NII imaging marker and CSF Aß42. When controlling with age, gender and APOE ε4 genotype, the partial correlations with CSF Aß42 was rpartial = -0.34 ($P < 0.001$) for NII cell diffusivity in the genu of corpus callosum (Fig. 1B) and rpartial = -0.30 ($P < 0.001$) for NII cell fraction in the posterior lateral capsule (Fig. 2B). Positive correlation between NII cell diffusivity with CSF tTau and pTau in the corpus callosum was observed.

CONCLUSION

The significant negative correlations between NII cellularity and CSF Aß42 suggest NII may be used to track the immune cell activation associated with abnormal ß-amyloid accumulation. NII holds promise to noninvasively study the role of inflammation during AD progression and the effect of treatments targeting immune response.

CLINICAL RELEVANCE/APPLICATION

Neuro-inflammation imaging holds promise to noninvasively study the role of inflammation during Alzheimer disease progression and the effect of treatments targeting immune response.

SSA19-03 Correlation of Lobar Cerebral Microbleeds with Amyloid, Perfusion, and Metabolism in Alzheimer's Disease

PURPOSE

Despite the well-documented relationship between lobar CMBs (lCMB) and Alzheimer's disease (AD), there is limited knowledge about the role of lCMB in AD pathology. To understand the nature of this relationship, we investigated the association between lCMB and total and regional amyloid load, perfusion and metabolism.

METHOD AND MATERIALS

Participants with AD, Mild cognitive impairment (MCI) and age-matched healthy controls were recruited through well-established memory services. Detailed cognitive assessments and cardiovascular (CV) history and risk factors were recorded. All participants were imaged with Pittsburg-Compound B (PiB)-, Fludeoxyglucose (FDG)-PET followed by 3T MRI with susceptibility-weighted-imaging (SWI). Early frames of PiB-PET (1-8 min) were utilized to estimate perfusion and late frames (40-70 min) to measure amyloid burden. FDG emission data was acquired from 60-90 minutes after injection. PET uptake was presented as standardized uptake value ratio (SUVR) using cerebellum as reference. Presence of lCMB in each anatomical region was documented and the association between lCMB and PET uptake in each lobe was measured using multiple regression models. The mean of PET SUVRs was also compared between groups using t-test.

RESULTS

In multiple regressions models adjusting for sex, age, education, CV risk factors and clinical diagnosis, presence of lCMB was associated directly with total ($p<0.001$) and regional ($p=0.01$) late PiB and inversely with early PiB uptakes ($p=0.04$). In MCI group, participants with lCMB had higher perfusion ($p=0.001$) and metabolism (0.03) compared to MCI without lCMB, while AD individuals with lCMB had lower perfusion ($p=0.03$) than those with no lCMB and no significant difference in their metabolism. Presence of lCMB also weakened the association between perfusion and metabolism ($R2 =0.2$ versus $R2 =0.49$).

CONCLUSION

There is a significant relationship between lCMBs and various markers of AD pathology. lCMB has spatial association with AB load and complex effect on perfusion and metabolism.

CLINICAL RELEVANCE/APPLICATION

lCMB could exacerbate and accelerate the neurodegenerative process in AD by affecting perfusion and metabolism. Regional association between lCMB and amyloid burden in PET suggests vascular amyloid could represent total amyloid load.

SSA19-04 Mismatch of Perfusion and Brain Function in Type 2 Diabetes with Normal Cognition: Potential Compensation for Cognitive Impairment?

PURPOSE

Type 2 diabetes mellitus (T2DM) is associated with increased risk of cognitive impairment and dementia, for which the disturbance in cerebral perfusion is an important etiology. The aim of this study is to explore the effect of T2DM on the coupling between cerebral blood flow (CBF) and cortical activation and its potential contribution to cognitive function.

METHOD AND MATERIALS

A total of 36 T2DM patients with normal cognition and 36 sex- and age-matched healthy subjects underwent arterial spin labeling imaging to compute CBF, resting-state functional MR (fMR) to identify the CBF-related network, and to calculate indicators of cortical activations, including functional connectivity strength (FCS), functional connectivity (FC) between region with decreased CBF and the whole brain, mean amplitude of low-frequency fluctuation (mALFF) and mean regional homogeneity (mReHo) of regions within CBF-related network. The CBF-cortical activation correlation coefficients, the so called CBF-cortical activation coupling, of regions in CBF-related network and its relationship with cognitive performance were compared between the 2 groups.

RESULTS

T2DM patients with normal cognition showed significantly reduced CBF in the rostroventral area of the left inferior parietal lobule, whereas increased FCS in left dorsal caudate. In T2DM patients, significantly increased CBF-related FCs were predominantly located in cognitive- and executive-related brain regions, including the middle frontal gyrus (MFG), fusiform gyrus (FuG), superior parietal lobule (SPL), and inferior parietal lobule (IPL). The CBF-FC coupling at IPL, SPL, and CBF-mReHo coupling at MFG were significantly increased in T2DM patients. FCs of CBF-related network was positively correlated with global cognition, whereas negatively correlated with episodic memory and executive function across all subjects.

CONCLUSION

Our findings demonstrated that the mismatched decreased CBF accompanied by increased FCs in CBF-related network plays a complementary role in T2DM patients with normal cognition. Increased neurovascular coupling might be a possible neuropathological mechanism of the preservation of cognitive function in T2DM patients.

CLINICAL RELEVANCE/APPLICATION

CBF and CBF-related FCs from fMR play a complementary role in early T2DM and are recommended as powerful biomarkers to explore the neuropathological mechanism of cognitive impairment and preservation.

SSA19-05 The Cortical-Limbic Structural Covariance Network as an Early Predictive Bio-Signature for Cognitive Impairment in Parkinson's Disease

Sunday, Nov. 25 11:25AM - 11:35AM Room: E351

Participants
Yueh-Sheng Chen, MD, Kaohsiung, Taiwan (*Presenter*) Nothing to Disclose
Meng-Hsiang Chen, Kaohsiung, Taiwan (*Abstract Co-Author*) Nothing to Disclose
Kun-Hsien Chou, Taipei, Taiwan (*Abstract Co-Author*) Nothing to Disclose

Chih Ying Lee, Kaohsiung, Taiwan (*Abstract Co-Author*) Nothing to Disclose
Wei-Che Lin, MD, Kaohsiung, Taiwan (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

In the present study, we sought to identify the epicenter and its associated structural network that targeted the cognitive

impairments in Parkinson's disease (PD). We then tested whether alterations of the structural network would predict future cognitive decline in PD patients.

METHOD AND MATERIALS

One hundred and one patients with PD (subgrouping into 3 groups [PD-normal (PDN), PD-mild cognitive impairment (PDMCI), PD-dementia (PDD)]) and 58 normal control volunteers underwent comprehensive neuropsychological testing and T1W volumetric MRI scans. Epicenters were identified by voxel-wise group comparison between PDN and PDD. Gray matter structural covariance network (SCN) were constructed using the epicenters as seeds. The SCN volume corrected by total intracranial volume was calculated in each individual to reflect the SCN integrity. The PDN group had follow-up neuropsychological testing one year after the initial exam to assess the status of conversion into cognitive impairment.

RESULTS

Bilateral amygdala and hippocampus were significantly atrophied in PDD as compared to PDN group. Analysis of bilateral amygdala/hippocampus SCN showed decreasing volume in PDD and PDMCI as compared to PDN group. The PDD group showed stronger covariance strength in the left prefrontal cortex as compared to the PDN group. The lower volume of bilateral amygdala/hippocampus SCN were associated with poorer cognitive function in all domains while lower volume in the prefrontal cortex was associated with poorer cognitive function in the attention and executive function domain. Smaller volume of bilateral amygdala/hippocampus SCN and left prefrontal cortex in the PDN patients can predict the conversion into PDMCI at one-year follow-up.

CONCLUSION

The cortico-limbic system is important in cognitive decline in PD patients. The atrophy of amygdala/hippocampus SCN and increased co-atrophy of the prefrontal cortex can early predict MCI conversion in PD patients with normal cognition.

CLINICAL RELEVANCE/APPLICATION

The analysis of cortical-limbic structural covariance network alteration can early predict MCI conversion in PD patients with normal cognition.

SSA19-06 Repetitive Transcranial Electrical Stimulation Produces Enhanced Resting Cerebral Perfusion in the Locus Coeruleus

Sunday, Nov. 25 11:35AM - 11:45AM Room: E351

Participants

For information about this presentation, contact:

matthew.sherwood.7.ctr@us.af.mil

PURPOSE

To evaluated the effect of repetitive left prefrontal transcranial electrical stimulation (TES) on cerebral perfusion (i.e., cerebral blood flow, CBF).

METHOD AND MATERIALS

11 healthy, active-duty, Air Force military members completed 3 experimental sessions on 3 consecutive days. Transcranial DC stimulation, a form of TES, was utilized to deliver 2mA to the left prefrontal cortex (approximately F3) for 30 min at each session. Stimulation began concurrently with a 30 min laboratory vigilance task. The cathode was placed on the contralateral bicep. Pre- and post-stimulation MRI acquisitions were conducted at each session. The MRI procedure included a 3D pseudo-continuous arterial spin labeling sequence to acquire resting CBF. A control group consisting of 9 subjects performed the same procedures except sham stimulation was provided (30 s of stimulation followed by 19.5 min of no stimulation). CBF maps were created from the raw ASL data using proton density maps and a single-compartment perfusion model. The CBF maps were registered to a reference space. Permutation testing compared changes in CBF from session 1 pre-stimulation to session 3 post-stimulation between groups and within-groups on a voxel-wise basis using 500,000 permutations. The permutation test results were cluster-corrected for multiple comparisons.

RESULTS

Widespread increases in perfusion, indicative of increased metabolism, were observed in the active stimulation group; however, general decreases were observed in a matched group receiving sham TES. Furthermore, perfusion increased significantly more in the active stimulation group across many areas of the brain. These increases originated in the locus coeruleus (LC) and spread extensively to regions in the neocortex supporting functions such as object recognition and top-down attentional modulation.

CONCLUSION

Altered CBF in the LC is indicative of enhanced metabolic activity as cerebral perfusion is neurovascularly coupled with glucose metabolism. This finding increases our understanding of the broad behavioral effects that have been demonstrated using left prefrontal TES.

CLINICAL RELEVANCE/APPLICATION

Altered production of norepinephrine has been linked with many neurologic disorders including Parkinson's disease, major depression disorder, and attention deficit hyperactivity disorder. Our findings implicate the potential for left prefrontal TES in the treatment of such disorders.

SSA19-07 Tract Based Spatial Statistics in Persons who Will Develop Alzheimer's Dementia: A Study from the Alzheimer's Disease Neuroimaging Initiative (ADNI)

cyrusraji@gmail.com

PURPOSE

To quantify differences in diffusion tensor imaging of persons who decline from normal cognition to Alzheimer's dementia compared to controls who do not develop dementia.

METHOD AND MATERIALS

All subjects were from ADNI2 (n = 20). Average age was 73.4 ± 3.9 years with age range 68.2-83.7 years. All subjects were age and gender-matched for comparison. The sample was 60% women and 40% men. Each subject received 3T MR imaging on either a Siemens or GE scanner for T1 volumetric imaging, MP-RAGE for Siemens or SPGR for GE. All DTI scans were obtained on a 3T GE scanner. Raw T1 and DTI DiCOM images were converted to NiFTI file format. Each scan was visually inspected for gross artifacts. Images were corrected for motion, eddy currents and skull-stripped using the fMRI software library (FSL). Fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity and radial diffusivity (RD) maps were also obtained via FSL's dtifit and FSLmaths tools and visualized for errors. Data were then processed through FSL's tract-based spatial statistics (TBSS) with default parameters. FA, MD, RD, and axial diffusivity values were extracted.

RESULTS

Of the 20 subjects, 10 experienced longitudinal cognitive decline and 10 remained cognitively normal. Of the 10 converters, 80% were MCI at baseline and converted to AD and of these 50% declined after 6 months and another 50% declined after 12 months. Of the remaining two converters, one declined from normal to mild cognitive impairment (MCI) to AD after 24 months and another subject experienced a similar trajectory after 48 months. Comparing global DTI metrics, there was a trend towards statistical significance with respect to lower global mean FA in converters compared to non-converters ($t = -.43$, $p = .07$). However, voxel wise analyses with TBSS showed statistically significant reductions in frontal white matter tracts in converters compared to non-converters as shown in Figure 1 (red arrows). There were no statistically significant differences in other global DTI metrics including RD, MD, and axial diffusivity.

CONCLUSION

Diffusion weighted MR imaging identifies quantifiable differences between AD converters compared to non-converters.

CLINICAL RELEVANCE/APPLICATION

Identification of non-invasive quantitative neuroimaging biomarkers that predict cognitive decline to Alzheimer's dementia is important for determining persons who may benefit from drug trials or modification of risk factors.

SSA19-08 MR Differences of Cerebral Small Vessel Diseases in AD and MCI Patients

jiangyuhan0728@163.com

PURPOSE

To evaluate and compare MRI manifestations of cerebral small vessel diseases (SCVD)among Alzheimer's disease (AD), mild cognitive impairment (MCI) patients and healthy controls (HC), and then to analyze the correlation between CSVD and cognitive score.

METHOD AND MATERIALS

Twenty-four AD patients (12 men and 12 women;mean age,73.08±8.39 yrs) and twenty-four cases of MCI (11 men and 13 women;mean age,70.08±8.5 yrs) were participated into this study. Twenty-two volunteers without cognitive dysfunction were also recruited as controls (11 men and 11 women; mean age,71.01±8.10 yrs). Their age, gender and education matched in three groups. All subjects underwent conventional sequences (including T1WI, T2WI and T2 Flair) and SWI on 3.0T MRI scanner. Enlarged perivascular spaces (EPVS) were counted and scored in basal ganglia (BG) and centrum semiovale (CS). Moreover, cerebral microbleeds (CMBs) and lacunar infarction (LI) were also counted, whileas white matter hyperintensity lesions(WMH) were graded and recorded. The Kruskal-Wallis test and Kolmogorov-Smirnov Z test were used to compare the ranked data between groups. Correlation between SCVD and MMSE were assessed by spearman correlation analysis.

RESULTS

In the BG, EPVS scores increased in AD group (2.08±0.77) than in MCI (1.29±0.46) and controls(1.09±0.29)($P<0.01$); no difference

was found between EPVS scores in MCI and controls (P>0.05). In the CS, EPVS scores in AD group (2.87±0.79) and MCI group (2.12±0.53) were significantly higher than that in controls (1.36±0.49) (P<0.01). There was no difference of cerebral microbleeds between three groups (P>0.05). The periventricular WMH and deep WMH in the AD group increased than in the controls (P<0.05). Compared to MCI group, AD group showed more severe in the periventricular WMH (P<0.01). The incidence of LI was most in AD group (58.3%, 14/24), in turn in MCI group (29.2%, 7/24) and in controls (18.2%, 4/22, P<0.05). In all data, EPVS in BG and CS, periventricular and deep WMH showed the negative correlation with MMSE score (r=-.072, -0.31, -0.56, -0.40; all P <0.05).

CONCLUSION

CSVD is more common in AD than in MCI patients, and EPVS and WMH have significant effect on cognitive impairment.

CLINICAL RELEVANCE/APPLICATION

CSVD is common in AD patients and is associated with the clinical status.

SSA19-09 Altered Functional and Effective Connectivity Patterns Based on the Subregion of Hippocampus in Young Apoeε4 Carriers: A Three-Year Follow-Up Study

Sunday, Nov. 25 12:05PM - 12:15PM Room: E351

Participants
Li Juan Zheng, MS , Nanjing, China (*Presenter*) Nothing to Disclose
Long Jiang Zhang, MD, PhD, Nanjing, China (*Abstract Co-Author*) Nothing to Disclose
Guang Ming Lu, MD, PhD, Nanjing, China (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

18502524467@163.com

PURPOSE

To determine whether the functional and effective connectivity based on the subregions of hippocampus altered in young APOE4 carriers with follow-up.

METHOD AND MATERIALS

Resting-state functional MRI data and neuropsychological scales were obtained for APOE4 (with the age 24.0±3.2 years old, 7 female and 6 male) and APOE3 carriers (with the age 22.9±1.6 years old, 12 female and 7 male) at baseline and three-year follow-up. The hippocampi were divided along the A-P axis, into three equal sections (sub1/2/3 respectively stands for the anterior, middle and posterior part of the hippocampus). The hippocampus- and sub- based functional connectivity (FC) patterns were compared by mixed effect analysis and further post-hoc analysis. The effective connectivity (EC) patterns among the altered regions, affected by APOE4-by-time interaction, were examined in APOE4 groups at baseline and follow-up. The correlation analysis was conducted between the values of altered FC or EC and neuropsychological scales

RESULTS

The APOE4-by-time interaction effect was evident in FC between sub3(L) and left middle and superior temporal gyrus (MTG/STG), sub2(R) and MTG/STG(L), and sub3(R) and anterior cingulate cortex(ACC). The Post-hoc analysis revealed decreased FC in sub3(L)-MTG/STG(L), sub3(R)-ACC, and increased FC in sub2(R)-MTG/STG(L) in APOE4 group at baseline when compared with APOE3 group. The APOE4 group at follow-up showed increased FC in sub3(L)-MTG/STG(L), sub3(R)-ACC and decreased FC in sub2(R)-MTG/STG(L) (all P<0.05, corrected by Gaussian random field with voxel-size P<0.01 and cluster-size P<0.05). The FC in sub3(L)-MTG/STG(L) at baseline and sub2(R)-MTG/STG(L) at follow-up correlated with the scores of scales both in APOE3 and APOE4 group. Besides, the APOE4 group showed increased EC separately from sub2(L) and MTG/STG(L) to sub3(L) among altered regions (the bilateral sub2/3, MTG/STG(L) and ACC). The values of changes in EC from MTG/STG(L) to sub3(L) positively correlated with the changed scores of delayed recall test (all P<0.05).

CONCLUSION

The left posterior part of hippocampus might be most vulnerable and susceptible to early modulation of interaction of APOE4 by time, which might be used as the longitudinal imaging-derived-phenotype in APOE 4 carriers.

CLINICAL RELEVANCE/APPLICATION

providing a new biomarker to predict the early neuroimaging alteration in the young carriers.

PURPOSE

To prospectively evaluate different quantitative parameters from contrast-enhanced transrectal subharmonic imaging (SHI) for the diagnosis of prostate cancer with histopathology as the reference standard.

METHOD AND MATERIALS

Fifty-five male patients scheduled for a transrectal systematic prostate biopsy were enrolled in this IRB-approved study. A 12-core sextant biopsy was done in each subject along with up to 6 additional targeted biopsies. Subjects were imaged with a transrectal IC5-9D ultrasound (US) transducer on a modified Logiq E9 system (GE Healthcare; Milwaukee, WI) operating in SHI mode (transmit/receive: 7.0/3.5 MHz). Two vials of the US contrast agent Definity (Lanteus Medical Imaging; N. Billerica, MA) diluted in 50 mL of saline were infused over 10 minutes. Images were obtained with transverse sweeps though the prostate using conventional US, color and power Doppler, as well as contrast harmonic imaging (HI), and SHI. Microbubble destruction pulses followed by motion-compensated maximum intensity projection (MIP) was evaluated in combination with HI and SHI. Imaging modes were rated on a five-point scale (1-5; benign to definitely malignant) for each sextant. Using MIP time intensity curves, parametric maps were generated at each biopsy location for the peak intensity (PI), time to peak (TTP), and estimated perfusion (EP as the slope of the wash-in). Parameters were compared to biopsy results.

RESULTS

Prostate cancer was found in 55 of 660 cores (8.33%) from 24 of the 55 subjects (43.64%). No significant difference between benign and malignant biopsy specimens were demonstrated for TTP (3.01 ± 1.52 vs 3.18 ± 1.56 s; p=0.44). Two quantitative SHI parameters showed a significant difference between benign and malignant biopsy cores: EP (25.69 ± 8.74 vs 30.09 ± 10.23 a.u./s; p=0.0007) and PI (123.85 ± 16.02 vs 129.66 ± 17.38 a.u.; p=0.014).

CONCLUSION

Quantitative SHI demonstrates significantly higher EP and PI at sites with prostate cancer.

CLINICAL RELEVANCE/APPLICATION

SHI appears to improve the diagnosis of prostate cancer relative to conventional transrectal US.

SSA20-02 Ultrasonic Spectrum Analysis of the RF Time Series Can Early Predict the Tumor Response to Chemotherapy in Preclinical Breast Cancer Models

lifei@sysucc.org.cn

PURPOSE

This study was aimed to assess whether ultrasonic spectrum analysis of radiofrequency (RF) time series using a clinical ultrasound system allows for the early prediction of the tumor response to chemotherapy in human breast cancer xenografts that imitate clinical responding and nonresponding tumors.

METHOD AND MATERIALS

Clinically responding (n=20; MCF-7) and nonresponding (n=20; MBA-MD-231) breast cancer xenografts were established in 40 nude mice. Ten mice from each group received either chemotherapy (adriamycin, 4 mg/kg) or saline as controls. Each tumor was imaged longitudinally with a clinical ultrasound scanner at baseline (day 0) and subsequently on days 2, 4, 6, 8 and 12 following treatment, and the corresponding RF time-series data were collected. Changes in six RF time-series parameters (slope, intercept, S1, S2, S3 and S4) were compared with the measurement of the tumor cell density, and their prediction performances of the treatment response were analyzed.

RESULTS

Adriamycin significantly inhibited tumor growth and decreased the cancer cell density in responders ($P < 0.001$) but not in nonresponders ($P > 0.05$). Fold changes of slope were significantly increased in responders two days after adriamycin treatment ($P = 0.002$), but not in nonresponders ($P > 0.05$). Early changes in slope on day 2 could predict the treatment response in 100% of both responders (95% CI, 62.9-100.0%) and nonresponders (95% CI, 88.4-100%).

CONCLUSION

Ultrasonic RF time series allowed for the monitoring of the tumor response to chemotherapy and could further serve as biomarkers for the early prediction of treatment outcomes.

CLINICAL RELEVANCE/APPLICATION

Because ultrasound imaging provided several major benefits such as the relatively low cost, portability and repeatability, and lack of radiation risks, our study built the foundation of further translational research to assess the clinical application of the RF time series to predict the treatment response in cancer patients without using any contrast agents.

SSA20-03 Electric-Field Induced Acoustic Tomography (EfAT) for In-Situ Monitoring of Tumor Ablation during Irreversible/Reversible Electroporation

Sunday, Nov. 25 11:05AM - 11:15AM Room: S102CD

Liangzhong Xiang, PhD, Norman, OK (*Presenter*) Nothing to Disclose

For information about this presentation, contact:

a.zarafshani@ou.eduxianglzh@ou.edu

PURPOSE

High intensity ultra-short pulsed electric fields applied across a cell to increase the membrane permeability, allowing non-permeant drugs, genes access (or tumor ablation) through the formation of nano-scale pores in the cell membrane, known as reversible (or irreversible in the case where nano-scale defects in the cell membrane is used for tumor ablation instead of drugs/genes delivery). For physicians, real-time monitoring of cancer treatment and characterization of the delivered electric field is very important for treatment planning and therapy efficacy monitoring. Many techniques i.e. MRI or MREIT are suggested to characterize this process, but currently cannot monitor the process during pulse delivery in real time and mostly used for pre-and post-stimulation exposure.

METHOD AND MATERIALS

A new imaging technique based on flow of electric field induced acoustic tomography is reported. The absorbed electric energy around the subject under test raises its temperature, thus leading to expansion effects. The expansion, then induces acoustic tomography images which can be acquired outside the body and consequently be used for real-time characterization and monitoring the electroporation process. These acoustic images made through the high-intensity and ultra-short pulsed electric fields that used in the electroporation process where combines the advantages of high-contrast electric field distribution and high-ultrasonic spatial resolution.

RESULTS

We captured different acoustic signals and corresponding ultrasonic images by changing the location of electric distribution in scale of mm and varying the electric field intensity (μs-ns 20kVcm-1-63kVcm-1) applied in irreversible and reversible electroporation process. The experimental results demonstrated a linear correlation between the measured acoustic signals and the intensity of the electric field.

CONCLUSION

The study results indicate that this new technique can potentially be used for monitoring the electric field distribution as a non-invasive, label-free technique for real-time, in situ monitoring of electroporation-based technologies for treatment and ablation cancer.

CLINICAL RELEVANCE/APPLICATION

for ECT and NIIRE, the treatment efficiency is correlated to electric field distribution. To ensure adequate electric field coverage of the treated tumor EfAT to mapping the eletric field distribution is used for treatment plannning and therapy efficacy monitoring in the clinic.

SSA20-04 Accuracy of Volumetric Measurements in the Breast: A Study of Comparing Ultrasound Tomography and Hand-Held Ultrasound

Sunday, Nov. 25 11:15AM - 11:25AM Room: S102CD

Participants
Rajni Natesan, MD, MBA, Houston, TX (*Presenter*) Officer, QT Ultrasound Labs
Bilal Malik, PhD,MS, Novato, CA (*Abstract Co-Author*) Employee, QT Ultrasound Labs
Lauralyn R. Markle, MD, Laguna Niguel, CA (*Abstract Co-Author*) Consultant, QT Ultrasound Labs
Vashita Dhir, MD, Beverly Hills, CA (*Abstract Co-Author*) Consultant, QT Ultrsound, LLC
Robin Terry, Novato, CA (*Abstract Co-Author*) Employee, QT Ultrasound, LLC

PURPOSE

This study assessed the accuracy of volumetric measurements acquired with ultrasound tomography (UST). UST imaging generates 3D speed-of-sound maps that can identify tissue types and measure lesion volumes. Since tumor volume doubling time is associated with growth rate and tumor biology, accurate measurement of tumor volume is critical for oncologic diagnosis, staging, and treatment.

METHOD AND MATERIALS

Six cylindrical agar phantoms were imaged using UST and hand-held ultrasound (HHUS). Each phantom contained 4 embedded "lesions" composed of irregular-shaped chicken breast with known volumes ranging from 1.3 cm3 to 7.4 cm3. Two board-certified breast imaging fellowship-trained radiologists independently performed blind interpretations of the UST and HHUS phantom images and calculated 24 lesion volumes. UST volumes were calculated with automated segmentation software (QT Ultrasound, Novato, CA). HHUS lesions were measured in 3 dimensions (a, b, c) and their volumes were calculated using 2 volume formulas: (1) (4/3)πr3 (with r = average of a, b, and c); and (2) (π/6)abc. These calculations were then statistically analyzed to determine the volumetric measurement accuracy of both UST and HHUS as compared to known true volumes calculated by water displacement methods.

RESULTS

The average lesion volume calculated from UST images was 3.93 1.55 cm3 and from HHUS was 6.39 2.61 cm3 (sphere) or 5.65 2.39 cm3 (ellipsoid), compared to the true average of 3.98 1.47 cm3. HHUS volumes were significantly larger than the true volumes with a mean over-estimation of 62.8% 36.9% cm3 (sphere) or 43.3% 32.6% cm3 (ellipsoid), whereas UST volumes agreed with the truth within measurement errors. Interobserver agreement was substantial (ICC = 0.95).

CONCLUSION

This study demonstrates that UST can accurately measure the volume of irregular-shaped masses, with superior accuracy than HHUS.

CLINICAL RELEVANCE/APPLICATION

Ultrasound tomography can accurately measure tumor volume, demonstrating its potential utility in guiding oncologic management and treatment.

SSA20-05 Evaluating Ductal Carcinoma in situ Progression via Tissue Oxygenation and Perfusion Using Photoacoustic and Contrast-Enhanced US

ryanamargolis@gmail.com

PURPOSE

To investigate tissue oxygenation and perfusion as predictors of the aggressiveness of ductal carcinoma in situ (DCIS) as well as the influence of physical exercise on these parameters as well.

METHOD AND MATERIALS

Twenty FVB/NJ and 10 Tg(C3-1-TAg)cJeg mice (Jackson, Laboratories, Bar Harbor, ME) were evenly split into active and control subgroups, where the active group had access to a Fisher Science exercise wheel. Changes in mammary gland vascularity and perfusion were monitored with a Vevo 2100 LAZR scanner (FujiFilm VisualSonics, Toronto, Canada) using a LZ-250 PA probe.

Photoacoustic imaging was used to measure tissue oxygenation. To assess perfusion quantification, each mouse received a retroorbital bolus injection of 10 µL of 3-4 µm sized microbubbles (Advanced Microbubble Laboratories, Boulder, CO). Imaging of the mammary gland was performed weekly over 6 weeks and the mice were weighed biweekly. Offline analysis was performed using Vevo CQ software.

RESULTS

For the FVB/NJ mice, weekly weight changes were lower for the active group than the control group (0.43±0.70 g vs. 0.99±2.31 g, p = 0.002). Conversely, changes in oxygenation were higher for the active group than the control group (11.16±19.30% vs. 7.77±26.73; p=0.38). There were no statistical differences for contrast wash-in rates (a measure of perfusion), or area under the curve between the two groups (p>0.25). For the SV40 Tag mice that naturally develop breast tumors, the weight changes were lower for the active group than control group (1.71±1.34 g vs. 2.57±1.51 g, p=0.0056). There was also a statistical significant decrease in oxygenation in the exercise group compared to the control group (-19.37±26.88% vs. 20.21±29.55%; p<0.001). Similarly, there were no statistical differences between the wash-in rate or area under the curve between the two groups (p>0.26).

CONCLUSION

Preliminary results indicate differences in tissue oxygenation between the FVB/NJ and SV40 Tag mice may become a predictive precursor for DCIS progression. The influence of exercise was shown by the weight changes, but the influence on DCIS progression is still being investigated.

CLINICAL RELEVANCE/APPLICATION

This study may potentially minimize breast cancer overtreatments by predicting the aggressiveness of DCIS in humans via tissue oxygenation measurements using ultrasound.

SSA20-06 A New Microfluidic Setup to Adjust Objectively 2D and 4D DCE-US Presets as an Alternative to Preclinical Studies

Sunday, Nov. 25 11:35AM - 11:45AM Room: S102CD

PURPOSE

Ultrasound tumor microvascularization assessment is a promising biomarker of patient response to anti-angiogenic drugs. Quantitative DCE-US imaging lacks dedicated phantoms featuring small vessels in order to optimize the image acquisition and define the preset parameters objectively. We propose a microfluidic setup dedicated to methodological development, and we compare it to a preclinical study on mice.

METHOD AND MATERIALS

Microfluidic setup The phantom was a 2.5x5x1cm3 block featuring cylindrical channels of diameters ranging from 145 to 450 µm. Sonovue (Bracco) was driven through the channels with very high reliability by a MFCS-EZ microfluidic flow controller (Fluigent SA, France). Flow rate was measured in real-time by a dedicated platform. An Aplio500 ultrasound scanner (Toshiba Medical Systems, Japan) with 2D and 4D 12MHz probes was used to acquire Contrast Harmonic Imaging (CHI) raw data. Quantification was made using UltraExtend FX software (Toshiba). The main parameters studied were mechanical index (MI), frequency (F), frame rate (fps), 4D volume angle (vol). *Preclinical study* 5 mice were imaged using the same 2D and 4D 12 MHz probes and injected with 100 µL Sonovue. 180 seconds raw data clips centered on the kidney were acquired and quantified using the scanner software. The same parameters were studied as on the microfluidic setup.

RESULTS

Microfluidic setup A new generation of microflow phantom enabled the precise control of 60-120 µL/min flow rates by a microfluidic pressure controller with a stable flow and under 5% variation over 3 minutes. After confirming the lack of microbubble destruction by the flow controller, the effects of MI, F, fps and vol were individually quantified. The best setup for optimal signal over noise ratio was MI 0.18, F h8.0 MHz, 4 fps, vol 30°. *Preclinical study* The best setup parameters were confirmed on the acquisitions on mice, however the in vivo variability of perfusion quantification was higher.

CONCLUSION

The microfluidic setup we developed can be used to perform reproducible tests and set up acquisition parameters objectively in DCE-US imaging modes. It is an alternative approach to preclinical studies, and is more objective than in vivo models.

CLINICAL RELEVANCE/APPLICATION

The new microfluidic setup was relevant to set up DCE-US imaging mode parameters in an objective way and to adjusting the presets in DCE-US 2D and 4D.

SSA20-07 Simultaneous MR and Ultrasound Image Acquisition in a Human Using a Hands-Free, MR-compatible, Volumetric Ultrasound Transducer for Image Guided Radiation Therapy

CONCLUSION

These first human images demonstrate that the hands-free, electronically steerable e4D transducer can acquire ultrasound images during a MR acquisition without impacting either the MR or ultrasound images quality. This technology may be applied to other image-guided procedures (e.g. proton therapy, biopsies, and drug delivery).

Background

This work addresses the need for a cost-effective and non-invasive real-time motion management platform for radiotherapy. We have developed the first ever hands-free, MR-compatible, electronically-steered, and real-time volumetric (e4D) ultrasound probe that will be used to directly track tumor or vessel motion during radiation therapy. The ultrasound images acquired during treatment will be coupled to a pre-treatment training image set consisting of a simultaneous 4D ultrasound and 4D MRI acquisition. The images will be rapidly matched using advanced signal processing algorithms, allowing for the display and verification of MR-based tumor/organ motion in real-time from an ultrasound acquisition.

Evaluation

The transducer contains 18,000 piezoelectric elements and beam forming and data acquisition electronics in the transducer housing. Currently, the probe is designed to have a maximum imaging depth of 15 cm, with 2 mm lateral resolution at 7 cm. The transducer acquires a 3D electronically-steered volume (4 vps) with a maximum sweep angle of 30o. Simultaneous MR and ultrasound images were acquired on a healthy volunteers liver using a GE 3T MR750 scanner. A fast spoiled gradient echo (FSPGR) multi-phase 2D sagittal acquisition with temporal acquisition of 4 fps was used for imaging. A 32-channel cardiac phased-array receiver coil was used with the transducer positioned under anterior elements. Ultrasound images were acquired in harmonic mode (1.7/3.3 MHz) at a rate of 4 fps using the transducer and a GE Vivid E95 system. Images were co-analyzed using MIM Maestro.

Discussion

No significant artifacts were detected during the acquisition of the MR and ultrasound images. Some low level susceptibility artifacts near the transducer in the MR image was detected, but this was well-contained within 1-2 cm of the surface and did not adversely effect the image quality.

SSA20-08 Optimization of a Subharmonic Dynamic Contrast-Enhanced Ultrasound Technique for Liver Tumor Imaging

Sunday, Nov. 25 11:55AM - 12:05PM Room: S102CD

PURPOSE

Conventional dynamic contrast-enhanced ultrasound (DCE-US) detects the first harmonic signal component arising mainly from the contrast agent (CA) microbubbles perfusing through the tissue, although the tissue itself also generates harmonics. Subharmonic

(SH) signal detection holds significant potential for increasing the sensitivity of tumor detection in the liver as only the CA generates subharmonics. This paper describes the optimization of the SH-DCE-US technique via bench-level experiments and its translation to a clinical scanner.

METHOD AND MATERIALS

Experiments were performed to maximize the signal from a commercial CA (SonoVue®, Bracco, Switzerland; default and an altered bubble size distribution) using a home-built microbubble characterization system with variable control over transmit beam center frequency and number of cycles. The optimal transmit beam parameters were translated to a commercial scanner (Aixplorer, Supersonic Imagine, France). A novel perfusion phantom, comprising different compartments mimicking healthy, diseased and necrotic tissue regions, was developed and used to validate the new technique on the scanner.

RESULTS

The maximum SH signal was measured for a transmit beam of 3 cycles centered at 1.9 MHz (i.e. SH signal at 0.95 MHz) for the native CA (57% bubble volume 4-10µm). The optimal transmit frequency increased to a more useful range of 2.3-2.5 MHz (SH signal at 1.15-1.25 MHz) in an altered CA with reduced polydispersity ((1-4µm; 99%/82% bubble count/volume, respectively). DCE time-intensity curves were produced on the clinical scanner using these optimal transmit beam parameters with the perfusion phantom, with improved quantification at depth of the microbubble signal using the new SH technique.

CONCLUSION

Optimal transmit beam parameters have been established for maximizing the SH signal in DCE-US scanning of the liver. Furthermore, a simple alteration of the CA's polydispersity shifted the optimal SH detection frequency above 1 MHz, which is the typical lower-frequency limit for curvilinear probes used for liver scanning. Improvements were demonstrated using a novel perfusion phanton.

CLINICAL RELEVANCE/APPLICATION

This paper demonstrates an optimized dynamic contrast-enhanced liver ultrasound imaging technique, using subharmonic signal detection with an easily-altered microbubble contrast agent formulation.

SSA20-09 US-Triggered Antibiotic Release from Novel Spinal Fusion Hardware

PURPOSE

To determine optimal acoustic parameters for destruction of a polymeric membrane surrounding a prophylactic-containing spinal reservoir. The long-term goal is to achieve ultrasound (US)-triggered release of antibiotics from within this spinal spacer to prevent post-surgical infection.

METHOD AND MATERIALS

Polylactic acid (PLA)-coated, methylene blue (MeB)-loaded polyether ether ketone (PEEK) spacers (0.785cm3) with a drug-loading reservoir were created in our labs. Coated spacers were submerged in water and insonated for 10 minutes using a Logiq E9 scanner (GE Healthcare, Waukesha, WI) with a C1-6 curvilinear probe, using power Doppler to rupture the PLA coating for MeB release. Frequencies evaluated were 1.7, 2.5, and 3.6 MHz, pulse repetition frequencies (PRFs) tested were 0.1, 3.5, and 6.4 kHz, and acoustic output (AO) powers tested were 30, 60, and 100%. MeB release was evaluated qualitatively against known MeB concentration standards immediately following insonation and again after 24 hours. Results were collected in triplicate and compared with a one-way ANOVA.

RESULTS

Membrane rupture increases with lower frequencies, but no significant difference was observed in release from the spacers at the frequencies evaluated (70-100% cumulative release, p=0.48). Therefore, 1.7 MHz was selected as optimal. This frequency was maintained, while PRF was varied. A PRF of 0.1 kHz resulted in significantly less immediate release (17.5±1.3%; p=0.021), but no difference was seen between PRFs of 3.5 kHz (32.5±2.5%) and 6.4kHz (36.3±5.4%, p>0.99). AO power was varied with 1.7 MHz and PRF 6.4 kHz. There was no significant difference in release between the AO powers (p>0.08). Uninsonated controls exhibited only 1.3±1.2% immediate release (p=0.031), and 6.8±2.8% cumulative release (p=0.021), confirming US-triggered release as opposed to passive leakage.

CONCLUSION

This study determined scanning parameters appropriate for US-triggered release of encapsulated prophylactics, as a first step towards deployment of this drug delivery system.

CLINICAL RELEVANCE/APPLICATION

This system will aggressively combat post-surgical bacterial infection with great versatility in applications for wide clinical impact.

PURPOSE

Scout scans are a mandatory part of CT examinations, but do not -yet- provide quantitative information. Purpose of this study was to develop and evaluate a method for areal bone mineral density (aBMD) measurement based on dual-layer spectral CT scout scans.

METHOD AND MATERIALS

A post-processing algorithm using a pair of 2D virtual mono-energetic scout images (VMSIs) was established in order to semi-automatically compute aBMD at the spine. The method was assessed based on repetitive measurements of the standardized European spine phantom (ESP) at the standard scout scan tube current (30 mA), at other tube currents (10 to 200 mA), as well as with fat-equivalent extension rings simulating different patient habitus, and was compared to dual-energy X-ray absorptiometry (DXA). In two female patients, the feasibility of the method was assessed in-vivo for vertebrae L1 to L4 and the results were compared to age-matched reference values. Finally, BMD was determined in a female patient population (n=31, age range 22-87 years old) with the proposed method, and T-scores were derived from the measurements, taking a young subset of the population as the reference.

RESULTS

Derived from standard scout scans, aBMD values measured with the proposed method highly correlated with DXA measurements (r=0.9925), and mean accuracy (DXA: 4.12%, Scout: 1.60%) and precision (DXA: 2.64%, Scout: 2.03%) were comparable. In particular, the scout scan-based method performed better than DXA at low BMD values (accuracy DXA: 8.3%, Scout:4.79%). Moreover, when assessed at different tube currents, aBMD values did not differ significantly ($p>=0.20$ for all), suggesting that the presented method could be applied to scout scans with different settings. Finally, data derived from sample patients as well as first T-score representations agreed well with BMD values and T-score trend from a reference age-matched population.

CONCLUSION

Based on dual-layer spectral CT scout scans, aBMD measurements were fast and reliable and highly correlated with DXA measurements. First measurements on patients were promising. Considering the number of CT acquisitions performed worldwide, this method could allow truly opportunistic osteoporosis screening at a larger scale.

CLINICAL RELEVANCE/APPLICATION

Dual-layer spectral CT frontal scout scans could provide fast and quantitative DXA-like BMD assessment at the spine and allow large-scale, opportunistic osteoporosis screening.

SSA21-02 Spectral CT Metal Artifact Reduction

Sunday, Nov. 25 10:55AM - 11:05AM Room: S103AB

Participants
Taly G. Schmidt, PhD, Milwaukee, WI (*Abstract Co-Author*) Research Grant, General Electric Company
Rina F. Barber, PhD, Chicago, IL (*Abstract Co-Author*) Nothing to Disclose
Emil Y. Sidky, PhD, Chicago, IL (*Presenter*) Nothing to Disclose

tal.gilat-schmidt@marquette.edu

PURPOSE

To evaluate a novel Spectral CT metal artifact reduction method through simulations and phantom experiments using a photon-counting detector.

METHOD AND MATERIALS

The proposed constrained 'one-step' Spectral CT Image Reconstruction (cOSSCIR) method addresses beam hardening due to metal by directly estimating basis material maps uisng a polyenergetic x-ray transmission model. The proposed method enables masking energy windows corrupted by metal on a ray-by-ray basis, for example masking only the lowest energy window in some rays while using information from higher energy windows. The cOSSCIR algorithm includes constraints that mitigate undersampling artifacts that occur when unreliable measurements through metal are masked. A Spectral CT acquisition of a pelvic phantom with Co-Cr-Mo hip prostheses was simulated with four energy windows. An experimental Spectral CT acquisition was performed with a CdTe photon-counting detector, three energy windows, and a phantom with and without metal. For both simulations and experiments, a weighted mask was applied to remove projection data corrupted by metal. cOSSCIR reconstruction was performed by decomposing into bone, water, and copper material maps and then combining the maps to form an effective monoenergetic image. Images were also reconstructed using filtered backprojection (FBP) with and without the Normalized Metal Artifact Reduction (NMAR) technique. CT number error in the region between the metal implants was compared.

RESULTS

In the simulation study, the cOSSCIR algorithm reduced the CT number error in the metal artifact streaking region to less than 1 HU error. In the experimental study, the CT number error was 7 HU for cOSSCIR reconstruction with weighted mask, 60 HU for cOSSCIR without masking, 40 HU for FBP +NMAR, and 212 HU error for FBP. The cOSSCIR images did not contain streak artifacts seen in the NMAR images.

CONCLUSION

The proposed Spectral CT metal artifact reduction method reduced shading artifacts to <1 HU error in simulations and 7 HU error in experiments, without introducing residual streak artifacts.

CLINICAL RELEVANCE/APPLICATION

Metal artifacts in CT images obscure structures, alter CT numbers, challenge diagnosis, and impede radiation therapy planning. The proposed method, which could also be applied to dual-KV systems, corrects metal artifacts without knowledge of the implant material.

SSA21-03 Areal Bone Mineral Density Estimation Using Dual-Energy Computed Tomography Topograms

Sunday, Nov. 25 11:05AM - 11:15AM Room: S103AB

Participants
Tristan Nowak, Forchheim, Germany (*Abstract Co-Author*) Grant, Siemens AG
Bernhard Schmidt, PhD, Forchheim, Germany (*Presenter*) Employee, Siemens AG
Natalia Saltybaeva, PhD, Zurich, Switzerland (*Abstract Co-Author*) Nothing to Disclose
Thomas G. Flohr, PhD, Forchheim, Germany (*Abstract Co-Author*) Employee, Siemens AG
Hatem Alkadhi, MD, Zurich, Switzerland (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Dual-Energy X-ray absorptiometry (DXA) is in wide clinical use for the diagnosis and monitoring of osteoporosis. Using DXA, a good estimation of areal bone mineral density (aBMD) can be extracted from two images acquired with different X-ray spectra by subtracting the influence of soft tissue on the total X-ray absorption and isolating the absorption of carbonated hydroxyapatite (HA). Since most clinically performed CT scans include a topogram as a 2D overview image, it would be beneficial to also employ these images for the diagnostic purpose of an aBMD estimation. A prerequisite for this approach is the acquisition of dual-energy topograms, either sequentially, or ideally, using a single scan. In this work, we compared quality and dose of aBMD measurements from a standard DXA (bone densitometry) scan with sequentially acquired dual-energy topograms.

METHOD AND MATERIALS

Two anterior-posterior (AP) topograms of a BMD calibration spine phantom (European Spine Phantom, QRM GmbH, Möhrendorf, Germany) were sequentially acquired using a dual source SOMATOM Force CT System (Siemens Healthcare GmbH, Forchheim Germany). In order to maximize spectral separation, tube voltages of 70 kV without and 150 kV with added tin filtration were chosen at tube current time products of 70 and 75 mAs, respectively. The phantom consists of water-equivalent plastic with diameters of 260 mm (lateral) and 180 mm (AP) and holds three anthropomorphic vertebrae, L1-L3, of varying HA content (50, 100 and 200 mg/cm^3) in the spongious part of the bone. A custom tool was developed to subtract soft tissue and create aBMD density maps from the input topograms. Deviations from the known aBMD values of 0.5, 1.0 and 1.5 g/cm^2 of the AP projections of vertebrae L1-L3 were evaluated.

RESULTS

The extracted values for vertebrae L1-L3 from the generated aBMD maps were in good agreement with the ground truth. The mean areal densities and standard deviations for L1, L2 and L3 were 0.493 ± 0.05, 1.01 ± 0.04 and 1.52 g/cm² ± 0.03, respectively.

CONCLUSION

Especially with regard to the advent of energy-discriminating, photon-counting detectors, the work presented here shows a promising new domain for spectrally acquired topograms. This technique might serve as an alternative to using dedicated DXA scanners.

CLINICAL RELEVANCE/APPLICATION

Areal bone mineral density measurement is feasible via topograms with sufficient energy separation acquired via dual-energy CT.

SSA21-04 Monochromatic CT Image Reconstruction via Deep Learning

Sunday, Nov. 25 11:15AM - 11:25AM Room: S103AB

Participants
Wenxiang Cong, Albany, NY (*Abstract Co-Author*) Nothing to Disclose
Ge Wang, PhD, troy, NY (*Abstract Co-Author*) Nothing to Disclose
Hongming Shan, Troy, NY (*Presenter*) Research Grant, General Electric Company

PURPOSE

Develop a deep-learning-based algorithm to achieve monochromatic CT image reconstruction from current-integrating raw data.

METHOD AND MATERIALS

In clinical CT, with a polychromatic x-ray source, raw data are collected in the current-integrating mode. This physical process is accurately described by an energy-dependent non-linear integral model. However, the non-linear model is too complicated to be directly solved for the image reconstruction, and often approximated as a linear integral model known as the Radon/X-ray transform, which basically ignores energy-dependent information. This model mismatch leads to inaccurate quantification of an attenuation image and significant beam-hardening artifacts. Here, we develop a deep-learning-based approach to address the mismatch between the computational process and the physical model. Our method learns a nonlinear transformation from big data to correct measured raw data in accordance with line integrals at a pre-specified monochromatic energy. A multi-layer perceptron (MLP) neural network is designed for this purpose, consisting of four layers, one input layer, two hidden layers, and one output layer. The sigmoid function is used for non-linear activation. The neural network is trained with the ADAM optimization. The training procedure is programmed in Python and the TensorFlow framework on a computer with a NVIDIA Titan XP GPU of 12 GB memory. A set of clinical dual-energy CT datasets of the human abdomen, collected on a GE Discovery CT750 scanner, are used in the training and testing stages to demonstrate the feasibility of the proposed methodology.

RESULTS

The optimization of the neural network has an excellent converging performance, achieving a high accuracy in the monochromatic projection estimation with a relative error of less than 0.2%, overcoming beam hardening effectively.

CONCLUSION

Our approach is capable of learning a nonlinear transformation from big data, making a step forward towards monochromatic imaging directly from single-spectrum energy-integrating data. This is a potential cost-effective alternative to dual-energy CT.

CLINICAL RELEVANCE/APPLICATION

The deep-learning-based reconstruction method may perform monochromatic CT imaging, allowing for applications in lesion detection and tissue characterization, and proton therapy.

SSA21-05 Evaluation of a Spectral Imaging Metal Artifact Reduction Algorithm Using a Novel Image Quality Phantom

Sunday, Nov. 25 11:25AM - 11:35AM Room: S103AB

Participants
Hilde K. Andersen, MSc, Oslo, Norway (*Presenter*) Nothing to Disclose
Anette Aarsnes, Oslo, Norway (*Abstract Co-Author*) Nothing to Disclose
Hildur Olafsdottir, Salem, NY (*Abstract Co-Author*) Research funded, Image Owl, Inc

David J. Goodenough, PhD, Myersville, MD (*Abstract Co-Author*) Consultant, The Phantom Laboratory
Anne C. Martinsen, Oslo, Norway (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the performance of a spectral imaging metal artifact reduction algorithm (GSI-MAR) using a novel phantom.

METHOD AND MATERIALS

A Catphan phantom with a CTP682 module (The Phantom Laboratory, Salem, NY, USA) was scanned on a GE Revolution 16 CT scanner (GE Healthcare, Milwaukee, WI, USA) with and without body annulus and with inserts of stainless steel, titanium and PMMA (control). Metal inserts had diameters of 0.5' and 0.25'. Spectral imaging scans were reconstructed in mono-energetic levels of 55 keV, 68 keV and 90 keV, with filtered back-projection (FBP), FBP with metal artifact reduction (MAR), 50% iterative reconstruction (ASIR-V) and 50% ASIR-V with MAR. Standard deviation (SD) as measures of streaking was derived from ROIs surrounding the inserts and in the outer part of the phantom. Low contrast detectability (LCD) close to the inserts was evaluated by two human observers. MTF and NPS were measured for all series.

RESULTS

Titanium did only introduce streaking close to the large insert. Stainless steel introduced large streaking artifacts. For the large titanium insert, MAR reduced SD from 23HU to 11HU without ring, and from 159HU to 14HU with ring. For the large stainless steel insert, MAR reduced SD from 61HU to 10HU without ring, and from 436HU to 23HU with ring. For the control, SD was 4HU without ring and 10HU with ring (all at 68 keV, same trend for 55 and 90 keV). Without the ring, LCD was close to the level of the control for the small inserts and the large titanium insert. For the large stainless steel insert, LCD decreased for 55 and 90 keV, and MAR improved LCD but not to the level of 68 keV and the control. With the ring, LCD decreased for all energies and inserts. For stainless steel, 90 keV had the best LCD, MAR improved LCD for 55 and 68 keV, but only to the level of 90 keV. For titanium, 68 keV had the best LCD, and MAR improved LCD for the small insert. Analyses of NPS and MTF are work in progress.

CONCLUSION

GSI-MAR reduced streaks from titanium and stainless steel and improved LCD close to metal. Optimal energy level and effect of MAR depends on metal type and size, as well as patient size.

CLINICAL RELEVANCE/APPLICATION

The performance of new metal artifact reduction algorithms in CT for different metals is not known. Catphan CTP682 module with metal inserts proved useful in evaluation of one such algorithm, GSI-MAR.

SSA21-06 Limits for Detecting Low Concentrations of Iodine with Dual-Energy Computed Tomography

Sunday, Nov. 25 11:35AM - 11:45AM Room: S103AB

Participants
Megan C. Jacobsen, BA, Houston, TX (*Presenter*) Nothing to Disclose

Rick R. Layman, PhD, Houston, TX (*Abstract Co-Author*) Researcher, Siemens AG

PURPOSE

Multiple studies in the literature have proposed diagnostic thresholds based on Dual-Energy Computed Tomography (DECT) iodine maps. However, it is critical to determine the minimum detectable iodine concentration for DECT systems to establish the clinical significance of various measured quantities for these image types.

METHOD AND MATERIALS

Seven serial dilutions of iohexol were made with concentrations from 0.03 to 2.0 mg iodine/mL in 50 mL centrifuge tubes. The dilutions and one blank with distilled water were scanned five times each in two scatter conditions: a 20.0 cm diameter (Head) phantom and a 30.0 cm x 40.0 cm elliptical (Body) phantom. We utilized six scanners from three vendors, including fast-kVp switching, dual-source, dual-layer detector, and split-filter DECT. Scan parameters and dose were matched as closely as possible across systems, and iodine maps were reconstructed using each vendor's software. Regions-of-Interest were placed centrally within each vial on the iodine map. Mean and standard deviation were calculated across the five scan acquisitions, and linear calibration curves were calculated for each scanner. Using standard analytical methods, the signal region corresponding to a 95% likelihood of measuring only water was defined as the Limit of Blank (LOB). Subsequently, the Limit of Detection (LOD) in the signal domain was defined as the LOB plus 1.645 times the standard deviation of the 0.5 mg/mL vial and was converted to a concentration using the calibration curves.

RESULTS

We found that the range of LOD was 0.021 - 0. 257 mg iodine/mL in the head phantom and 0.113 - 0.547 mg iodine/mL in the body phantom. Higher kVp levels on a given system generally performed better than lower kVp settings in the body phantom.

CONCLUSION

DECT systems available in today's marketplace can detect iodine concentrations as low as 0.113 mg I/mL in an anthropomorphic body phantom, which corresponds to an enhancement of approximately 2.8 HU at 120-kVp.

CLINICAL RELEVANCE/APPLICATION

DECT iodine quantification is a potential imaging biomarker, and we define detection limits for iodine measurements across multiple DECT systems, under which iodine cannot be reliably detected.

SSA21-07 Radiation Dose Efficiency of Multi-Energy CT for Simultaneous Imaging of Multiple Contrast Agents

PURPOSE

Multi-energy CT (MECT) has been proposed for imaging multiple contrast agents simultaneously, which may allow multi-phase data

to be acquired in one single scan, potentially reducing radiation dose. This work aims to evaluate the dose efficiency of MECT in two potential applications: iodine/gadolinium (I/Gd) for liver imaging and iodine/bismuth (I/Bi) for small bowel imaging.

METHOD AND MATERIALS

Dose efficiency was experimentally evaluated for I/Gd and for I/Bi by comparing a single-scan MECT (MECT_1s) protocol and a traditional two-scan single-energy CT (SECT_2s) protocol. For SECT_2s, an abdominal phantom containing two sets of I samples was designed to mimic enhancement at late arterial and portal-venous phases. For MECT_1s, I/Gd samples were used, with I enhancement corresponding to the late arterial phase and Gd enhancement to the portal-venous phase. Data were acquired on a SECT (120kV) for SECT_2s, and on a dual-energy CT (DECT: 80/Sn150kV or 90/Sn150kV) or a photon-counting-detector (PCD) CT (140kV [25 50 75 90keV]) for MECT_1s, with the total radiation dose from the two scan protocols matched. A generic image-based material decomposition method was used to determine the densities of I/Gd/water, based on which CT biphasic images were synthesized. The noise levels on the original images acquired with the SECT_2s protocol and the synthesized images generated with the MECT_1s protocol were compared. The dose efficiency for I/Bi was evaluated in a similar way except for the phantom design. For SECT_2s, a different abdominal phantom was used, containing one set of I samples and one set of Bi samples mimicking the arterial and enteric enhancement, respectively. For MECT_1s, I/Bi samples was used.

RESULTS

For I/Gd, the noise level with the MECT_1s protocol was 500-1600% higher than that with the SECT_2s protocol, given the same total dose. For I/Bi, the noise level with the MECT_1s protocol was 110-230% higher.

CONCLUSION

Single-scan MECT imaging using two contrast agents (I/Gd and I/Bi) is intrinsically dose inefficient compared with traditional multiple SECT scans, particularly for I/Gd. The dose efficiency of MECT is highly dependent on the contrast materials used for a particular application.

CLINICAL RELEVANCE/APPLICATION

Use of a single-scan MECT protocol for multi-phase liver and small bowel CT imaging is very dose inefficient compared with a traditional dual-scan SECT protocol.

SSA21-08 Liver Lesion Localization and Classification with Convolutional Neural Networks Comparing Conventional and Spectral Computed Tomography

PURPOSE

To localize and classify hepatic lesions with convolutional neural networks (CNNs) and evaluate the performance for different conventional and spectral computed tomography (CT) data.

METHOD AND MATERIALS

Contrast-enhanced liver CTs of 172 patients (33 with cysts, 57 with hypodense metastases and 82 healthy) were collected from a dual-layer spectral CT. Automatic liver segmentation was used. The localization and classification tasks were split into two stages: The first CNN was trained to localize hepatic lesions and produce heatmaps showing the location. Only the disease type and no segmentation ground truth was needed for the training. The heatmaps were used to automatically cut a region of interest (ROI) around the predicted lesion. In the second stage, the ROIs were used to train an additional CNN for the classification between healthy, cyst and metastasis. The final evaluation was performed on previously un-seen patient data. All experiments were compared for conventional CT data, reconstructed virtual monoenergetic images (VMIs) and iodine concentration maps. The classification performance was evaluated with precision, recall, accuracy and F1-score. The localization results on the test set were compared to the segmentation ground truth. The distance between lesion predictions and true lesions and the localization accuracy were evaluated.

RESULTS

The classification of the first CNN for healthy vs. lesion achieved a recall of 0.890, 0.855, 0.798, 0.874, 0.822 for 40 keV, 70 keV and 100 keV VMIs, iodine maps and conventional images, respectively. The localization accuracy and distance between true and predicted lesions presented the best results for low energy VMIs (40 - 70 keV) and iodine maps, outperforming the conventional data. The classification of ROIs into three classes reached the highest accuracy with 70 keV VMIs (84.5 %) compared to conventional data (83.5 %).

CONCLUSION

Using CNNs to localize lesions, cut ROIs and perform lesion classification offers a robust automatic workflow. Low energy VMIs show

using CNNs to localize lesions, cut ROIs and perform lesion classification offers a robust automatic workflow. Low energy VMIs show several benefits compared to conventional CT: Small lesions were detected with higher accuracies, heatmap results were more reliable and metastases and cysts were classified better.

CLINICAL RELEVANCE/APPLICATION

Using convolutional neural networks and spectral CT data for the automatic localization and classification of hepatic lesions has the potential to significantly aid the diagnostic decision process.

SSA21-09 Realistic Liver Tissue Surrogates for CT Phantom Studies Can Accurately Quantify the Benefits and Limitations of? Reduced kV Imaging in CT

Sunday, Nov. 25 12:05PM - 12:15PM Room: S103AB

PURPOSE

To assess the utility of a liquid tissue surrogate for the liver (LTSL) to emulate the CT attenuation characteristics of contrast-enhanced liver parenchyma and lesions as a function of tube potential, lesion contrast, phase of enhancement, and phantom size.

METHOD AND MATERIALS

A 3D-printed, fillable phantom was used to emulate liver parenchyma and focal lesions. First, we compared the CT attenuation of LTSL-iodine and water-iodine solutions at 80, 100, 120, 140 kV to published patient data. Based on these results, we emulated liver parenchyma in late arterial phase (LA: +92HU at 120kV) and portal venous phase (PV: +112HU at 120kV) using LTSL-iodine. Additional LTSL-iodine solutions emulated hyperattenuating lesions during the LA-phase (lesion-to-parenchyma contrast (CLP) = +5 to +50HU) and hypoattenuating lesions during the PV-phase (CLP = -5 to -50HU). Fat-equivalent plastic rings emulated medium and large patients. Each combination of CLP, phase of enhancement, and phantom size was imaged at 80, 100, 120, 140 kV at constant radiation dose. CT attenuation, CLP, and CNRLP were assessed. A theoretical model estimated CT attenuation, CLP, and CNRLP as a function of tube potential and lesion contrast which was compared to the measured data.

RESULTS

LTSL-iodine more accurately emulated the CT attenuation of contrast-enhanced liver parenchyma compared to water-iodine solutions. The theoretical model was confirmed by the empirical measurements using LTSL-iodine solutions: CT attenuation, CLP, and CNRLP increased when the tube potential decreased ($P<0.001$). This trend was independent of lesion contrast, phase of enhancement, and phantom size. The absolute improvement in CLP and CNRLP at reduced tube potentials, however, was inversely related to the magnitude of CLP at 140kV.

CONCLUSION

LTSL accurately emulated the CT attenuation characteristics of contrast-enhanced liver parenchyma and lesions at different tube potentials, lesion contrast, and phase of parenchymal enhancement. The relative improvement in CLP and CNRLP at reduced tube potentials was independent of lesion contrast, phase, and phantom size while the absolute improvement decreased for low-contrast lesions.

CLINICAL RELEVANCE/APPLICATION

Liquid tissue surrogates offer a promising tool for liver emulation in multi-energy CT phantom studies. Low contrast lesions, which are most difficult to detect in clinical routine, benefit less from low kV-imaging than high contrast lesions.

PURPOSE

To evaluate the effectiveness of a slice thickness reduction technique in computed tomography(CT) scans using convolutional neural network(CNN)-based super-resolution(SR) network for improving the sensitivity of lung nodule detection in thick section CT scans.

METHOD AND MATERIALS

We collected 100 sets of CT scans with identical acquisition protocols that were differentiated only by the slice thickness (1mm, 3mm, and 5mm). By employing CNN-based SR network, we trained the model to learn the residuals between synthesized thin section slices and real thin section slices. We used 80 sets of CT scans for training, 5 sets for the validation and the remaining 10 sets were used for quantitative evaluation. We separately collected 100 sets of CT scans (also with 1mm, 3mm, and 5mm slice thickness) with one biopsy-confirmed nodule per scan(46 solid nodules and 54 non-solid nodules, size ranges 6-12mm) to evaluate the effectiveness of the slice thickness reduction techniques for improving the lung nodule detection performance in thick section CT scans. The computer-aided detection(CAD) system used for the evaluation of lung nodule detection performance was internally developed with LUNA16 dataset, which contains 888 CT scans with slice thickness less than 3mm.

RESULTS

When slice thickness was reduced from 3mm to 1mm, the peak signal-to-noise ratio(PSNR) and structural similarity index(SSIM) were 30.9624 and 0.8142 respectively; when slice thickness was reduced from 5mm to 1mm PSNR and SSIM were 29.2620 and 0.7439 respectively. In the nodule detection task, all solid and non-solid nodules were detected by the CAD system using 1mm slice thickness scans(100.0% recall). However, 2 solid nodules were missed when using 3mm slice thickness scans (95.7% recall) while their corresponding synthetic 1mm scans improved the recall to 97.8% (1 missed solid nodule). Recall of scans with 5mm slice thickness was 89.1% and 85.2% while their synthetic 1mm scans improved the recall to 100.0% and 96.3% for solid and non-solid nodules respectively.

CONCLUSION

Our CNN-based SR method generates synthetic thin section slices from thick section slices which improve lung nodule detection performance using CAD.

CLINICAL RELEVANCE/APPLICATION

Robustness to acquisition protocol is essential for reliable lung CAD systems. Our slice thickness reduction technique may improve the robustness of CAD systems when applied to CT scans with various slice thickness.

SSA22-02 An Image Enhancement System for Disease Diagnosis

PURPOSE

Varying background intensity levels in medical images increases the difficulty of reading images and of identifying abnormal image regions. Windowing and leveling techniques are performed on the entire image, which fails to account for regional differences in image intensity. A method which normalizes image regions by expected image intensity in that particular region could improve diagnostic accuracy of scans.

METHOD AND MATERIALS

This technique is demonstrated for 18F-NaF PET/CT scans of 37 metastatic prostate cancer patients with a total of 1,751 bone lesions. Each image was divided into 19 skeletal regions, such as the humeri, ribs, or ilium, and thresholds were determined for each region. For this work, statistically optimized regional thresholding (SORT) determined thresholds by performing ROC optimization to determine detection thresholds in each bone region that maximize combined sensitivity and specificity for the detection of bone lesions. Finally, image voxels in each region were normalized by dividing the intensity values by the corresponding regional threshold. The detection rate and visibility of lesions was compared between the SORT normalized image and the image windowed at the lesion detection threshold recommended in literature (SUV=10 g/mL).

RESULTS

SORT windowed images, which used 18 different normalization values (SUV range: 3-13 g/mL), improve detection of lesions with higher sensitivity (96% for SORT, 83% for SUV=10 g/mL) while retaining high specificity (97% for SORT, 97% for SUV=10 g/mL). Regional normalization images increased the visibility of lesions by reducing the number of adjustments to windowing required and setting background across the image to values lower than 1.

CONCLUSION

Region-specific windowing of medical images can not only make an image easier for radiologists to read, but also assist in the identification of abnormal image regions, effectively reducing the amount of time required to read medical images. Regional windowing in this work was performed using thresholds optimized for disease detection; however, thresholds could be derived from other techniques, such as population mean healthy uptake in a region.

CLINICAL RELEVANCE/APPLICATION

Unlike traditional windowing or leveling, region-specific windowing can account for regional differences across an image, thus reducing the amount of time and effort required to read medical images.

SSA22-03 Evaluation of an Automated Deformable Mapping Technique with and Without External Fiducial Markers to Relate Corresponding Lesions in Digital Breast Tomosynthesis and Automated Breast Ultrasound Images

canngree@umich.edu

PURPOSE

To test an automated deformable mapping method for registering corresponding lesions in digital breast tomosynthesis (DBT) and automated breast ultrasound (ABUS) images with and without the use of external fiducial markers.

METHOD AND MATERIALS

A CIRS multi-modality breast phantom containing 20 lesions was employed and imaged with DBT (upright positioning with craniocaudal (CC) compression and mediolateral oblique (MLO) compression), and ABUS (supine positioning with anterior-to-chest wall compression). Eight external fiducial markers (gel pads containing 1-mm glass beads) were attached to the surface of the breast phantom prior to the imaging. The reconstructed images were segmented using manual (ABUS) and semi-automated (DBT) techniques. An automated mapping method generates, deforms, and relates the resulting models of the breast for registration of lesions between the DBT (CC or MLO) and ABUS image sets. Performance was assessed by the number of matched paired lesions and measures of the distances between the centers of mass (dCOM) of corresponding lesions.

RESULTS

The maximum number of lesions that could be matched was 18 because 2 of the 20 lesions were too close to the chest wall to be visible in the reconstructed DBT images. For mapping of DBT-CC to ABUS without markers, 14 of the 18 lesions were matched and the mean dCOM was 13.64 ± 6.25 mm. With markers, 17 of the 18 lesions were matched and the mean dCOM was 12.83 ± 6.03

mm. For mapping of DBT-MLO to ABUS without markers, 8 of the 18 lesions were matched and the mean dCOM was 9.32 ± 2.82 mm. With markers, 17 of the 18 lesions were matched and the mean dCOM was 12.25 ± 5.75 mm.

CONCLUSION

This work demonstrates the potential for using this deformable mapping technique to identify related lesions between two DBT views and ABUS images. This method shows improved lesion correlation with the use of external fiducial markers. This should improve radiologists' characterization of breast lesions which should reduce patient callbacks and unnecessary biopsies. Future work will include an IRB-approved proof of concept study with patient data for registration between DBT and ABUS images.

CLINICAL RELEVANCE/APPLICATION

This works demonstrates the use of an automated deformable registration technique between two DBT views and ABUS images and shows potential in improving the characterization of breast lesions between these modalities.

SSA22-04 Medical Image Fusion Using M-Band Wavelet Transform for Radiotherapy

Sunday, Nov. 25 11:15AM - 11:25AM Room: S103CD

Participants
Satishkumar Chavan, Mumbai, India (*Abstract Co-Author*) Nothing to Disclose
Abhijit D. Pawar, MD, Pune, India (*Abstract Co-Author*) Nothing to Disclose
Sanjay Talbar, Nanded, India (*Presenter*) Nothing to Disclose

abhijitpawar.rad@gmail.com

CONCLUSION

The fused images using proposed method provides the best out of both CT and MRI. The proposed fusion scheme has potential application in precise localization and delineation of lesions in treatment planning of radiotherapy.

Background

Radiation oncologists need information from both the Computed Tomography (CT)and Magnetic Resonance Imaging (MRI) sequences for precise outlining of tumour in radiotherapy. The proposed work aims to create new enriched image using medical image fusion of CT and MRI slices. The spectral features from source slices are extracted using M-band Wavelet Transform (MBWT).MBWT is separable, orthogonal transform with a perfect reconstruction property. It provides high directional sensitivity and finer spectral resolution. The average for low frequency subbands and maxima for high frequency subbands are used as fusion rules. The inverse transform reconstructs visually enriched fused image.This fused image is an excellent assistance to the radiation oncologist for delineation of tumour to prepare precise treatment plan.

Evaluation

In this work, total 39 sets of CT and MRI slices are used. The qualitative evaluation of the work is done in context with visual perception, contrast enhancement, confidence to lesion delineation and usefulness in treatment planning. Three expert radiologists rated fused images on the scale of 0 (poor) to 4 (excellent).The quantitative evaluation involves fusion metrics viz.entropy (En), image quality index (IQI), edge quality index (EQI), and mean structural similarity index measure (mSSIM) which are useful for quality, similarities with source images, and edge preservation.

Discussion

The fused images using proposed method provide better retention of the anatomical structures and visualization of lesions as compared to the state of art wavelet techniques as presented in Figure 1. The average score by three radiologists for fused images using presented work is 3.87.In quantitative evaluation, the fusion parameters are calculated and they give highest values for all the fused images using proposed method which indicate that proposed technique outperforms over other fusion techniques.

SSA22-05 Using Texture Analysis to Optimize Reconstruction Parameters

Sunday, Nov. 25 11:25AM - 11:35AM Room: S103CD

Participants
Kenneth Nichols, PhD, New Hyde Park, NY (*Presenter*) Royalties, Syntermed, Inc;
Christopher Caravella, New Hyde Park, NY (*Abstract Co-Author*) Nothing to Disclose
Christopher J. Palestro, MD, New Hyde Park, NY (*Abstract Co-Author*) Nothing to Disclose

knichols@northwell.edu

PURPOSE

In providing SPECT phantom quality assurance images to accrediting agencies, it is not obvious whether it is preferable to submit reconstructions performed using typical clinical (CLIN) protocol processing parameters, or to follow agencies' filtered backprojection (FBP) suggestions. We applied texture analysis metrics to determine the degree to which these choices affect equipment capability assessment.

METHOD AND MATERIALS

Phantom data were processed for 128 SPECT scans acquired for 32 Mcts for 10 gamma cameras, using 666-814 MBq 99mTc in cylindrical water baths with Plexiglas inserts of 6 sphere & rod sizes. Reconstructions were performed following agencies' suggestions of FBP & Hanning filtering (cutoff = 1.0) & Chang attenuation correction. Algorithms written in IDL v8.4 computed texture analysis gray-level-co-occurrence matrix (GLCM) entropy, with sphere contrast computed by fitting radial count profiles to 3rd order polynomial curves. ROC analysis established optimal discrimination thresholds using as the reference standard dichotomous visual readings of a medical imaging physicist, who graded sphere & rod visibility without knowledge of texture analysis values. The same phantom was used to collect 13 additional data sets with a dual detector SPECT camera equipped with a 4-slice non-

diagnostic CT scanner, reconstructed by FBP & by the manufacturer's default settings for clinical bone SPECT/CT protocols by OSEM (10 subsets; 2 iterations) & Butterworth filtering (cutoff = 0.5, order = 5), incorporating attenuation correction using the CT scan. GLCM computations were compared for FBP & CLIN reconstructions.

RESULTS

Optimal criteria for best agreement with visual scores for spheres was contrast (81±1% accuracy), & for rods was entropy (97±1% accuracy). For the 13 new acquisitions, by there criteria, more rods would have been visible for FBP than CLIN (46% versus 39%, p = 0.02), & more spheres (57% versus 40%, p = 0.0003), with greater sphere contrast (28±21% versus 19±18%, p < 0.0001). Rod entropy & sphere entropy were significantly different for FBP & CLIN reconstructions (-13.5±3.1K versus -14.6±2.8K, p < 0.0001 & -3.1±1.4K versus -4.6±3.9K, p = 0.0001), & favored detecting rods & spheres by FBP over CLIN.

CONCLUSION

Texture analysis can help in obtaining optimal results for equipment test data.

CLINICAL RELEVANCE/APPLICATION

Texture analysis provides a useful basis for choosing among image reconstruction options.

SSA22-06 Real-Time Deformable Image Registration for MRI-Guided Radiotherapy

gcsharp@partners.org

CONCLUSION

Real-time deformable image registration is a viable strategy for tracking organs in MR-guided radiotherapy. It is a promising approach for next-generation applications including beam tracking and real-time plan optimization.

Background

MR-guided radiotherapy has the capability to acquire 2D cine-mode images of patient cross sections in near real time. These images are used for monitoring of patient position and motion management using respiratory gating. Beam tracking is a radiotherapy strategy where the therapy beam continuously follows the target position based on real-time sensing. To enable beam tracking, the position of the intended target and avoidance structures must be identified in real-time. This abstract investigates real-time deformable image registration as an approach for MR-guided radiotherapy.

Evaluation

Registration accuracy and speed were retrospectively evaluated on sagittal plane cine-mode video sequences from nine stomach cancer patients. The video resolution was 100 x 100 pixels, with a pixel spacing of 3.5 mm. Images were registered to a reference image at the beginning of the sequence. Accuracy was evaluated by comparing manually drawn contours of the stomach with a warped reference contour. A total of 90 images, 10 from each patient, were annotated and analyzed. Speed was measured for the registration only, with file I/O excluded. B-spline registration was performed using plastimatch, with GPU-accelerated sum of squared difference cost function, and multicore-accelerated curvature regularization. To assess real-time performance, computation time was limited to 200 milliseconds.

Discussion

B-spline image registration ran at 8.8 +/- 2.0 milliseconds per iteration, which allowed 22 iterations to be performed. Registration accuracy was estimated to be 2.2 +/- 1.1 mm, using the center of mass of the manually drawn contours as the standard. Dice coefficient of the stomach was found to be 0.90 +/- 0.03. Approximately 90 percent of the computation time was used to compute regularization, we estimate that implementing this routine on the GPU will allow 100 iterations to be performed within 200 milliseconds.

SSA22-07 MR T2 * Parameter Imaging Based on DANTE Black Blood Prepared Sequence and Modified JSENSE Reconstruction Method

Sunday, Nov. 25 11:45AM - 11:55AM Room: S103CD

Participants
Yanan Ren, Zhengzhou, China (*Presenter*) Nothing to Disclose
Jingliang Cheng, MD,PhD, Zhengzhou, China (*Abstract Co-Author*) Nothing to Disclose

1554847793@qq.com

CONCLUSION

Multi-contrast images can be jointly recontructed by modified Jsense method with effective removal of the residual aliasing artfact at a high acceleration factor. Accurate T2* maps are obtained by DANTE-GRE due to its high SNR and effective blood signal supression.Phantom experiments demonstrated that the incorporation of modified Jsense and DANTE-GRE may outperform conventional multi-echo GRE T2* mapping.

Background

Quantitative analysis of T2* value is an effective tool to reflect iron content of human tissue in MRI, which are closely related to Mediterranean anemia.A new MRI pulse sequence and a modified reconstruction method were proposed to improve accuracy of T2* measurement. Specifically, DANTE prepared sequence is selected to supress blood signals and modified reconstruction method based on JSENSE is proposed to improve image quality and reduce scan time.

Evaluation

A numerical bloch simulations were established on DANTE prepared sequence to prove the velocity sensitivity and to select parameters.Several phantom experiments completed by DANTE-GRE realized more accurate T2* quantification with blood suppression compared with multi-echo GRE and MSDE-GRE sequence.The PSNR and HFEN were chosen to assess the quality of coil sensitivities and multi-contrast images recontructed by SENSE,Jsense and modified Jsense algorithm with acceleration factors of 2, 3 and 4. At last,ROIs in T2* maps obtained both in phantom and vivo were evaluted between DANTE-GRE sequence and modified Jsense method with former convential methods.

Discussion

The phantom results validate the superiority of modified Jsense algorithm in increaseing smoothness of multi-channel coil sensitivities and decreasing artifacts of multi-contrast images at a high acceleration factor.However,images of the first echo recovered by modified JSENSE achieve lower HEEN and higher PSNR compared to the last echo which has lower SNR due to its intrinsic T2* decay. By combining modified Jsense algorithm with DANTE-GRE sequence which could further acquire more image information and better image quanlity, more accurate T2* maps could acquire since the artifacts originating from flowing blood are effectively supressed.

SSA22-08 Automatic Cardiac Ventricle Segmentation from CT Images Using Fully Convolutional Neural Networks

PURPOSE

Acute pulmonary embolism (PE) is an emergent condition with three month mortality rate of 15%. Presence of PE is most often confirmed using Computed Tomography Pulmonary Angiography (CTPA). Mortality from PE is usually caused by overload of the right ventricle. The quantification of the right ventricular to left ventricular diameter ratio has been proved to be a quantitative prognostic marker for staging acute PE. Despite strong evidence for RV/LV as a prognostic marker in PE it is not always reported because it suffers from high interobserver variability and manual effort to measure. This work investigates automating the first step in an automated RV/LV CAD tool: ventricle segmentation.

METHOD AND MATERIALS

Fifty CTPA scans were used for this study (20 from cad-pe.org and 30 from a closed dataset). The ground truth segmentations were created by an imaging expert. This work developed a convolutional neural network (CNN) capable of segmenting the left and right cardiac ventricles from a 2D CT slice. The CNN was based on the U-Net. The training data consisted of 43 cases, the validation data consisted of 2 cases, and the test data consisted of 5 cases. The network was trained on 2D slices. To test the performance the CNN was passed all slices from a series and the largest morphologically connected region for each output class (RV and LV) was kept as the final segmentation. The CNN was trained with the original data and with an augmented data set where each slice passed to the network during training underwent a series of perturbations consisting of: 1) flipping, 2) noise injection, 3) deformation, and 4) random erasing.

RESULTS

The CNN trained on the original dataset has an average Dice coefficient of 0.96 on the training data and 0.90 on the testing data. The CNN trained with data augmentation had an average Dice coefficient of 0.94 on the training data and 0.94 on the testing data.

CONCLUSION

The CNN was able to create quality ventricle segmentations with only 43 scans in the training dataset, and the set of data augmentations significantly improved the performance on the test dataset.

CLINICAL RELEVANCE/APPLICATION

Accurate reporting of RV/LV can improve the diagnosis and staging of acute PE, but it is currently underreported because of interobserver variability and high manual effort. Automating this calculation could increase the rate and quality of RV/LV reporting, thereby improving patient care in emergency departments.

SSA22-09 Multi-institutional Deep Network for High Performance Sorting of Over 3000 AP and PA Chest Radiographs

Sunday, Nov. 25 12:05PM - 12:15PM Room: S103CD

tjrhines@uchicago.edu

PURPOSE

The classification of chest radiographs as anteroposterior (AP) or posteroanterior (PA) is important for their interpretation and any subsequent analysis and diagnosis. DICOM header information is often incomplete, and 328 of the 2364 (14%) chest radiographs acquired at our institution lacked the required information for AP/PA classification.

METHOD AND MATERIALS

Using a chest radiograph dataset from our institution, a convolutional neural network with AlexNet architecture was trained from scratch. 1475 AP and 713 PA radiographs were used, with 65% for training, 20% for step-wise validation, and 15% for testing. After training was complete, the network was tested on an independent set of 500 AP and 500 PA images from the National Institutes of Health chest radiograph dataset.

RESULTS

The independent test set yielded an AUC of 0.97 ± 0.0046, with less than 9% (89 of 1000) of radiographs misclassified. Of the images misclassified, several were improperly oriented or included a number of radiopaque medical devices. Our institutional dataset was used for training because of its high image quality and the lack of image imprinted "AP" or "PA" labels. Many images in the NIH dataset contain imprinted AP/PA labels, prompting their exclusion from the training dataset to avoid training the network to simply look for the imprinted label for the classification.

CONCLUSION

This model shows multi-institutional generalization of a trained network for the task of classifying AP and PA radiographs. A primary application of this network is for automated classification of the AP/PA view within the clinical workflow. The high AUC achieved demonstrates that the classification can be performed with high accuracy. Training the model took 4.5 minutes and testing 10,000 images took 130 seconds. Due to its speed, the classification technique could be applied without disruption of clinical workflow.

CLINICAL RELEVANCE/APPLICATION

To ensure appropriate classification and correct labeling of an image as AP or PA, a trained convolutional neural network can be used clinically with high accuracy and efficiency.

PURPOSE

Fatigue, the most common acute and subacute toxicity of partial or whole brain radiation therapy (WBRT), significantly decreases quality of life for patients, abrogating the benefit afforded by improved tumor control. The objective of the study is to evaluate the roles of neuroinflammation and orexin neuron activity in the pathogenesis of fatigue induced by clinically relevant WBRT fractionation.

METHOD AND MATERIALS

Adult male Sprague-Dawley rats received WBRT, 4 Gy in 5 daily fractions, or sham irradiation. Home cage locomotor activity (LMA) was continuously monitored using a photobeam system. Food intake and body weight were collected weekly. Cerebrospinal fluid (CSF) and brain sections were collected at fatigue onset, peak, and recovery. CSF orexin concentration was measured using radioimmunoassay. RNA was isolated from homogenized brain sections and inflammatory and oxidative expression patterns were evaluated using quantitative PCR. The data were compared to physician-reported fatigue, and orexin and cytokine CSF protein levels collected pre- and post-radiation from a cohort of 11 pediatric patients receiving proton radiation for primary brain cancer. Data were analyzed by t-test or 2-way ANOVA with post hoc Bonferroni corrected t-test. Significance was set at $P<.05$.

RESULTS

LMA was decreased in WBRT-treated rats starting following the first fraction and continued to decrease until reaching a nadir following the 5th and final fraction. LMA slowly recovered after that point, returning to baseline. Food intake and weight gain were significantly reduced in WBRT-treated rats, recovering to match sham rats within 2 weeks of the first fraction. The onset of fatigue is associated with widespread neuroinflammatory gene expression and decreased CSF orexin levels, which resolves as fatigue improves. Orexin levels were decreased and cytokine levels increased in CSF samples from patients for whom fatigue was recorded as a toxicity during treatment.

CONCLUSION

Brain radiation-induced fatigue is associated with neuroinflammation and decreased orexin levels in both preclinical and clinical samples. These data provide potential therapeutic avenues to address this disabling and pervasive toxicity of brain radiation.

CLINICAL RELEVANCE/APPLICATION

Neuroinflammation and orexin signaling appear to underlie brain radiation-induced fatigue, providing potential therapeutic targets.

SSA23-02 Translocation Frequency in Patients with Repeated CT Exposure: Comparison with CT-Naive Patients

Sunday, Nov. 25 10:55AM - 11:05AM Room: E353A

mmhoan@gmail.com

PURPOSE

To compare translocation frequency between patients with repeated computed tomography (CT) exposure and CT-naïve patients and to assess the relationship between radiation exposure and translocation frequency.

METHOD AND MATERIALS

This study was approved by our institutional review board. 48 cases with repeated CT exposure and 48 age- and sex-matched CT-naïve controls were prospectively enrolled in this single-institution study. Absorbed dose using dose-length product was used as a metric for radiation exposure and translocation frequency was assessed by using chromosome-specific fluorescent hybridization probes. The comparison of translocation frequency between cases and CT-naïve controls was performed by using Wilcoxon test (paired samples) and the relationship between radiation exposure and translocation frequency was assessed by partial correlation coefficient.

RESULTS

A statistically significant difference was present in translocation frequency between cases and CT-naïve controls (P = .0003). The median translocation frequency was 7 (95% confidence interval: 6, 8) for cases and 4 (95% confidence interval: 3, 6) for controls. By using translocation frequency as the response variable and radiation exposure (accumulated, maximum, and mean) as the effect variables, statistically significant correlation was found between accumulated radiation exposure and translocation frequency (r = .4279, P = .0030).

CONCLUSION

Chromosomal translocation was more common in patients with repeated CT exposure than CT-naïve patients, and a positive association was noted between accumulated radiation exposure and translocation frequency.

CLINICAL RELEVANCE/APPLICATION

Our results added evidence favoring a non-threshold response for radiation-associated cancer induction at low-level radiation exposure in medical practice.

SSA23-03 DNA Damage in Peripheral Blood Lymphocytes Induced By Low-Dose Chest CT: Comparison with Standard Dose Chest CT

Sunday, Nov. 25 11:05AM - 11:15AM Room: E353A

PURPOSE

The purpose of this study was to evaluate the DNA damage in peripheral blood lymphocytes induced by a low-dose chest CT scan using γ-H2AX foci as a DNA damage maker.

METHOD AND MATERIALS

We obtained institutional review board approval and the written informed consent from 217 patients, who were prospectively enrolled in this study. A total of 146 patients underwent low-dose chest CT (120 kV, 50 mAs, pitch factor 1.39), and 71 patients underwent standard-dose chest CT (120 kV, AEC, pitch factor 0.813). Blood samples were obtained before and after CT scan. Lymphocytes were isolated and stained against γ-H2AX (phosphorylated histone variant H2AX). The number of γ-H2AX foci in at least 4,000 lymphocytes was analyzed automatically with fluorescence microscopy. Significant differences between the number of foci were tested by using paired t-test, Wilcoxon test.

RESULTS

There were no significant difference in the character of patients between low and standard dose chest CT groups. The mean dose length product was 132 mGy·cm in low-dose CT and 455 mGy·cm in standard-dose CT groups, respectively. There was no significant difference in the baseline level of γ-H2AX foci between low and standard dose groups before CT examination.The numbers of γ-H2AX foci of patients in low-dose CT group before and after CT scan were 0.90 (standard deviation: 0.50) and 0.93 (0.51), respectively. There was no significant difference in the number of γ-H2AX foci before and after low-dose CT. The numbers of γ-H2AX foci in standard-dose CT group increased from 1.00 (0.45) to 1.07 (0.48) after CT scan. In contrast to the low dose group, the number of γ-H2AX foci in the standard dose group showed significant increase after CT (p=0.025).

CONCLUSION

Radiation effect by a low-dose chest CT was too low to be detected by γ-H2AX assay.

CLINICAL RELEVANCE/APPLICATION

γ-H2AX assay may be useful to determine the optimal radiation dose for low-dose CT in lung cancer screening

γ-H2AX assay may be useful to determine the optimal radiation dose for low-dose CT in lung cancer screening.

SSA23-04 A Novel Molecularly Targeted Radiotherapeutic Agent (MTRT) to Deliver Immunomodulatory Radiation to Multiple Pediatric and Adult Solid Tumors

PURPOSE

Radiation therapy (RT) has been shown in preclinical studies to enhance the efficacy of several types of immunotherapies. However, traditional external beam radiation therapy (EBRT) is typically only delivered to a few sites of disease, with larger field sizes being associated with systemic lymphopenia. Because many patients have widespread disease, it is nearly impossible for them to benefit from the efficacy enhancements afforded by immunotherapies using standard RT. Conversely, our RT delivery approach using a novel, tumor-selective form of molecularly targeted radiation therapy (MTRT), Y90-NM600, may augment tumor specific immune-priming by delivering RT to multiple sites of disease.

METHOD AND MATERIALS

Syngeneic mice were inoculated with tumors from adult and pediatric solid tumor lines B78 (melanoma), LLC (lung), MOC1 (Head and Neck), 4T1 (breast), Panc02 (Pancreas), GL261 (high grade glioma), K7M2 (Rhabdomyosarcoma), NXS2 and 9464D (neuroblastoma). Mice were injected with 250 µCi of Y86-NM600 and scanned via PET/CT at 2, 24, 48, and 72 h. Organs were then harvested for bio-distribution (BioD) via gamma scintigraphy. Another cohort of mice with bi-lateral B78 flank tumors were treated with 12 Gy EBRT to a primary tumor and anti-CTLA4 and were randomized to be treated w/wo 50 µCi MTRT. Tumor growth and survival was monitored. All mice with complete response (CR) were re-challenged with B78.

RESULTS

PET/CT and BioD data showed preferential uptake of NM600 in all tumor lines with highest uptake in Panc02 pancreatic tumors (10-fold increase of uptake in tumor compared to bone marrow, 2-fold increase compared to spleen). In our therapeutic 2-tumor trial, addition of MTRT resulted in decreased tumor growth ($p < 0.05$) of both primary and secondary tumors when combined with immune checkpoint inhibitor and EBRT (primary tumor) compared to a matched cohort randomized to just EBRT (primary tumor) and anti-CTLA4 alone. 50% of mice in the MTRT arm had a complete response and memory to B78 re-challenge compared to 0% in the no MTRT (EBRT + anti-CTLA4 alone) arm.

CONCLUSION

NM600 is a novel form of MTRT that shows preferential uptake in multiple solid tumors and can deliver immunomodulatory RT to distant tumors to increase response rates to T cell checkpoint blockade.

CLINICAL RELEVANCE/APPLICATION

MTRT sensitizes metastatic cancer cells to immunotherapy and improves response rates to systemic immune checkpoint blockade therapy.

SSA23-05 Identifying the Effect of Hereditary Factors on Radiation-Induced Cardiac Toxicity Using Novel Genetic Rat Models

Sunday, Nov. 25 11:25AM - 11:35AM Room: E353A

Participants

ams530@case.edu

PURPOSE

Radiation therapy is used in most cancer patients, but dose is limited by damage to normal tissue. The use of defined genetic models to assess radiation toxicity, followed by genetic mapping of radiosensitivity phenotypes, will allow for maximization of tumor dose while limiting normal tissue toxicity. In this study, we utilize consomic rats, which are genetically identical except that one chromosome is inherited from a second inbred rat strain.

METHOD AND MATERIALS

Adult male and female Salt Sensitive (SS) rats and SS.BN3 consomic rats, (SS background with Brown Norway chromosome 3), received image-guided localized whole heart radiation at a dose of 24 Gy or 9 Gy x 5 fractions. Echocardiograms with strain analysis were performed at baseline, 3, and 5 months. The student's t-test was used to compare values. RNA-seq from left ventricle samples at 1 and 10 weeks post radiation was performed and analyzed with IPA software.

RESULTS

Our previous studies have demonstrated that the SS.BN3 tumors are more radiosensitive than SS tumors. In the 24 Gy study, cardiac toxicity increased in SS compared to SS.BN3 male and female rats. End diastolic volume (EDV), a measure of ventricular dilation, was elevated after radiation in SS rats (EDV: 0.62 vs 0.49 ml, $p<0.01$). Systolic function measured with ejection fraction (EF), and contractility measured with radial strain, were lower in SS rats at 5 months (EF: 81 vs 94%, $p<0.01$, radial strain: 33 vs 68%, $p<0.01$). Left ventricular mass was elevated at 3 months in SS rats ($p<0.001$), and moderate-to-large pericardial effusions were present in 6/6 SS rats compared to 1/7 SS.BN3 rats at 5 months. Similar results are seen with the 9 Gy x 5 fractions. Gene expression analysis comparing SS and SS.BN3 females showed inflammatory and mitochondrial pathways with greatly altered expression, most notably at 1 week post-radiation.

CONCLUSION

These data show that SS rats are more sensitive to cardiac radiation than SS.BN3 rats, demonstrating the role of heritable factors in determining cardiac radiosensitivity. Gene expression analysis identified a number of cardiac-related targets on chromosome 3 for future studies of radiation protection. Further genetic mapping will aid in narrowing the causative target(s) for potential therapies.

CLINICAL RELEVANCE/APPLICATION

This project has the potential to enhance the effectiveness and toxicity profile of radiation therapy in cancer and to delineate new therapeutic targets.

SSA23-06 Role of Radio-Immunotherapy in the Treatment of Local and Distant Tumors in Prostate Cancer

Sunday, Nov. 25 11:35AM - 11:45AM Room: E353A

sayeda_yasmin-karim@DFCI.Harvard.edu

CONCLUSION

These results suggest that the use of SRB for sustained in-situ delivery of CD40 antibody could significantly enhance the abscopal effect of radiotherapy in treating prostate adenocarcinoma.

Background

Metastasis is the cause of death in most cancers including prostate. It has been observed by Mole and others that radiotherapy at one site may lead to regression of metastatic cancer at other sites, which were not irradiated; this phenomenon is called 'abscopal' effect. Unfortunately, this regression is not predictable. Some studies have observed an enhancement by systemic application of immunoadjuvants, which also has limited application because of generalized adverse effect. The purpose of this study is to evaluate the enhancing the abscopal effect of radiotherapy (RT) by in-situ delivered anti-CD40 using Smart Radiation Biomaterials (SRB) in the treatment of prostate cancer where treatment in one site (location) able to cure the tumors in other locations of the body.

Evaluation

A syngeneic mouse model of prostate adenocarcinoma was generated in both flanks of C57/BL6 background mouse. The palpable sized tumor of right flank was treated as randomized cohorts: control, treatment with 5 Gy of RT, anti CD40 antibody (20 µg/tumor), and in combination. Another cohort was created by sustained delivery of anti CD40 antibody using SRB where SRB material by itself demonstrates some degree of antineoplastic activity in our previous studies. A Small Animal Radiation and Research platform (SARRP) was used for image-guided RT at 220 kVp. Our result shows that in-situ application of antiCD40 antibody with radiation significantly enhances the effect of radiotherapy ($p<0.01$), whereas using the SRB for AntiCD40 delivery in situ further enhances the survival ($p<0.001$). Reduction of tumor volume was observed in both sides. 2 out of 5 mice showed total regression of the untreated tumors in the RT+SRB delivered AntiCD40 group.

Discussion

These promising findings provide a good basis for further/ongoing studies investigating RT and CD40 antibody dosing and scheduling and use of SRB for sustained in-situ delivery of such immunoadjuvants to further optimize the treatment outcomes with minimal systemic toxicities.

SSA23-07 Imaging and Treatment of Primary and Metastasized Tumors Through Immunotherapy Using Targeted Antigen-Capturing Nanoparticles with Serum Amyloid A1 along with Radiation and PD-L1 Blockade

PURPOSE

We aimed to image and treat primary and metastasized tumors in vivo using microcapsules that release antigen-capturing nanoparticles (AC-NPs) with serum amyloid A1 (SAA1) in three radiation sessions under PD-L1 blockade.

METHOD AND MATERIALS

For session 1, liposome-protamine-hyaluronic acid nanoparticles (LPH-NPs) containing 5% iopamiron and 400 μg anti-PD-L1 Ab were mixed with 1 mL 4.0% alginate, 3.0% hyaluronate, and 1 μg/mL P-selectin solution and incubated with 0.5 mM FeCl2 with 1 μg/mL a4ß1 Ab. Microcapsules were injected intravenously (IV) into BALB/c mice with primary LM17 tumors in the left hind leg and lung metastases. After 9 h, primary tumors were exposed to 10 or 20 Gy 60Co γ-rays. For session 2, AC-NPs generated by nanoprecipitation of 4 mg/ml polylactic-co-glycolic acid (PLGA) and 1000 ng/ml SAA1 were mixed with the cocktail described above and sprayed into 0.5 mM FeCl2 and 1 μg/mL anti-P-selectin Ab. Microcapsules (1 × 1010) were injected IV. After 9 h, tumors were irradiated as before. For session 3, 4 cGy 60Co whole-body γ-rays were administered at 24 h intervals for 5 d.

RESULTS

In session 1, anti-a4ß1 microcapsules accumulated around primary and metastatic tumors and were detected by CT. Microcapsules released P-selectin and anti-PD-L1 Ab in response to the initial irradiation. In session 2, microcapsules accumulated around the primary tumor via a P-selectin Ag-Ab reaction. PLGA AC-NPs and SAA1 were released after the second radiation dose. PLGA AC-NPs captured tumor-derived protein antigens released by the second radiation dose and transported them to SAA1-recruited and activated dendritic cells (DCs) that drove cross-priming of CD8+ T cells. In session 3, primed antitumor CD8+ T cells were activated by whole body radiation. These treatments significantly increased the antitumor effect (EF 1.7) and reduced metastasis by 74.3%.

CONCLUSION

Our CT-detectable microcapsules exhibited targeted AC-NP-mediated immunotherapeutic and abscopal effects, which could be used to advance tumor diagnoses and treatments.

CLINICAL RELEVANCE/APPLICATION

Targeted AC-NP-mediated immunotherapy with SAA1 directed by radiation enhanced the primary and metastatic antitumor effects of radiotherapy under PD-L1 blockade.

SSA23-08 Evaluation in Predicting Radiotherapy Efficacy for Esophageal Carcinoma Using Magnetic Resonance Diffusion-Weighted Imaging

PURPOSE

To evaluate magnetic resonance diffusion-weighted imaging (MR-DWI) technique in predicting the efficacy of radiotherapy for esophageal cancer

METHOD AND MATERIALS

Two related tests were performed in this experimental study. Test 1 included 40 Eca-109 nude mice models with esophageal cancer xenogrfts (test group=24; control group=16), and Test 2 included 42 and 42 mice models in test and control groups, respectively. The test group was given a single dose of 15Gy (6MV X-rays) during radiation therapy. In Test 1, sixteen time points included at 1 day before and 1 day after radiotherapy and then very two days during radiotherapy until 29th day. In the time points, all mice models underwent MRI scan with T1WI, T2WI, and DWI. In Test 2, MRI scans were performed at seven time points until 29th day and pathology results were obtained immediately after scans. The tumor volume and ADC value were evaluated in Test 1 and ADC values were compared with pathological cell density and necrosis in Test 2

RESULTS

Test 1, the growth doubling time was 17 days in test group and 5 days in control group. ADC values in test group rapidly increased at the 3rd day (highest at the 7th day) and then gradually decreased and returned to pre-therapy levels from the 17th day. In control group, the ADC values gradually decreased from the first day and kept at a low level from the 9th day. In Test 2, tumor cell density decreased from the 3rd day in test group compared with a gradual increased (highest at the 5th day) and then decreased in control group. Cell density in test group was lower than that in control group from the 3rd day after radiotherapy ($P<0.05$). ADC values were negatively correlated with cell density ($rs=-0.703$, $p=0.000$). The radio of necrosis of tumor in test group was higher than that in control group after the 3rd day ($P<0.05$). ADC values were positively correlated with the tumor necrosis ($rs=0.658$, $p=0.003$).

CONCLUSION

MR-DWI values could change earlier than morphological size during radiotherapy for esophageal cancer and ADC values showed good correlations with pathology findings, which has the potential in predicting the efficacy of radiation or other therapy.

CLINICAL RELEVANCE/APPLICATION

provide theoretical basis for the rational application of this technique in clinical practice

SSA23-09 Pseudoprogression versus Progression: The Role of Diffusion MRI During Immunotherapy for Solid

Tumor

PURPOSE

The aim of our study is to evaluate the role of diffusion-weighted MR sequences in the study of patients undergoing immunotherapy for stage IV solid tumors. The study aims to identify patients with pseudoprogression by calculating ADC and to differentiate them precociously from patients with true progression.

METHOD AND MATERIALS

Between September 2017 and March 2018 were evaluated with MRI with diffusion-weighted sequences (b value up to 800) 8 patients treated with immunotherapy (4 with renal cell carcinoma, 2 with pulmonary adenocarcinoma and 2 with melanoma). 11 target abdominal lesions were considered, positioning a ROI for the calculation of ADC in MRI performed at the beginning of therapy (RMt0), at the second infusion cycle (RMt1) and concomitantly with the revaluation TC, at approximately 8- 9 weeks (RMt2) after the start of treatment. Patients were staged at t0 and re-staged at t2 with toraco-abdominale and head contrast enhanced CT (TCt1 and TCt2) and were therefore classified as: progression (PD), partial response (PR), stable disease (SD) or pseudoprogression (PP) according to immuno-RECIST criteria.

RESULTS

Among the 8 patients evaluated, 2 died during immunotherapy (PD). Of the 6 patients on therapy, based on the immuno-RECIST criteria, 1 was considered PD, 1 PR, 3 were SD and 1 was definied in pseudoprogression (PP). The pseudoprogression is represented by a dimensional increase of the target lesion at t2. The ADC values calculated in the three MRI exams performed during immunotherapy are not significantly changed (mean ADC RMt0 0.71 ± 0.14, ADC RMt1 0.91 ± 0.39, ADC RMt2 0.76 ± 0.16).

CONCLUSION

Immunotherapy in solid tumors causes a transient increase in intratumoral lymphocyte infiltrate changing cell density in the lesion. The target lesions evaluated after the start of immunotherapy showed changes both in size and ADC value. The main limitation of our study is represented by the small number of patients currently evaluated.

CLINICAL RELEVANCE/APPLICATION

Despite an increase in size of target lesions in solid tumors (pseudo progression) ADC values calculated in MRI during immunotherapy are not significantly changed.

SSA24-01 Transarterial Computed Tomographic Angiography in Patients with Renal Function Impairment Undergoing Endovascular Aortic Repair

Sunday, Nov. 25 10:45AM - 10:55AM Room: S502AB

Participants
Giovanni F. Torsello, MD,BA, Berlin, Germany (*Presenter*) Nothing to Disclose

giovanni.f.torsello@gmail.com

PURPOSE

Endovascular aneursym repair (EVAR) of aortic aneurysms is the treatment of choice in most cases. Computed tomography angiography (CTA) is crucial in the preoperative planning and postoperative surveillance. Renal function impairment secondary to high volumes of contrast media however limits pre- and postoperative assessment especially of complex aortic aneurysms. The aim of this study is to evaluate the safety and diagnostic value of a novel technique in the setting of patients undergoing EVAR.

METHOD AND MATERIALS

Between January 2011 and August 2016, 145 patients with chronic kidney disease underwent transbrachial placement of an angiography catheter in the ascending aorta for i.a. contrast medium administration in the setting of a CTA. 45 patients with normal kidney function and aortic aneurysms were included in the analysis as a control group. Primary endpoint was the change in serum creatinine. Secondary security endpoints were access site complications and cerebrovascular accidents. Imaging quality endpoints were attenuation levels and contrast-to-noise-ratios in predefined vessels, validated by intraclass correlation coefficients.

RESULTS

Mean creatinine change was -.12 mg/dL, mean GFR change was 2.15% in the intervention group. There were two (1.3%) false aneurysms and one access site hematoma (0.7%). Two cerebrovascular accidents (1.3%) were transient. Transarterial CTA attenuation values varied between 228.98 (±78.66) and 266.21 (±110.82) Hounsfield units (HU), and 306.35 (±63.27) to 321.39 (±70.12) HU in the control group. The mean amount of contrast medium used in the catheter group was significantly reduced (31.70 ±5.82 mL) compared to a standard dose of 120 mL in the control group ($p = 0.001$). Contrast-to-noise ratios varied between 9.1 (±4.8) and 11.1 (±4.4) in the different segments. Intraclass correlation coefficients between the readings were very good (0.987-0.992).

CONCLUSION

This study demonstrates that a catheter-based transarterial computed tomographic angiography is a safe and efficacious way to evaluate patients with aortic aneurysms, both prior to and after endovascular aneurysm repair.

CLINICAL RELEVANCE/APPLICATION

Transarterial CTA is a safe means of assessing complex aortic aneurysms and yields high imaging quality for preoperative assessment and postoperative follow-up in patients with decreased renal function.

SSA24-02 Morphological Changes Within 365 Days Predict Late Adverse Events in Uncomplicated Type B Aortic Dissections

PURPOSE

Patients with medically treated type B aortic dissection (TBAD) remain at significant risk for late adverse events (AEs). We hypothesize that not only initial morphological features, but also their change over time are associated with late AEs.

METHOD AND MATERIALS

Baseline and 188 follow-up CT-scans (median and interquartile range: 4 years [2-5]) of 47 patients with acute uncomplicated TBAD were retrospectively reviewed. Morphologic CT imaging features were qualitatively and quantitatively assessed at baseline and each follow-up. Medical records were reviewed for late AEs, defined according to current guidelines. Predictive value of changes of morphological features (aortic diameter, size of intima tear, number of secondary tears, length of dissection, circumferential extent of false lumen and false lumen thrombosis) within 365 days for AEs was assessed using Cox proportional hazard regression with time-dependent covariates. Significant predictors were combined into a prediction model (cut-off p-value for model inclusion $p<0.15$)

RESULTS

21 AEs occurred in 47 patients. Multivariate analyses revealed following predictors for late AEs: maximum major aortic diameter: (HR=1.03[0.99-1.07] per mm increase p=0.06), number of secondary tears: (HR=1.02[0.90-1.15] per tear number increase p=0.80), area false lumen thrombosis: (HR=1.07[1.01-1.14] per mm2 increase p=0.03). The model with significant predictors showed following significant independent predictors: major aortic diameter: (HR=1.03[1.01-1.06] per mm increase $p<0.01$) and area false lumen thrombosis: (HR=1.07 [1.01-1.14] per mm2 increase p=0.03).

CONCLUSION

Increase in aortic diameter and false lumen thrombosis area within 365 days after onset are both significantly associated with greater risk of late AEs.

CLINICAL RELEVANCE/APPLICATION

Patients with increase of false lumen diameter and thrombosis within the first year after TBAD may benefit from shorter follow-up intervals and evaluation thereafter.

SSA24-03 Aneurismal Sac Remodeling After Nellix Endovascular Aneurysm Sealing System (EVAS) in Patients with Abdominal Aortic Aneurysm (AAAs): A Magnetic Resonance Imaging (MRI) Study

Sunday, Nov. 25 11:05AM - 11:15AM Room: S502AB

PURPOSE

The Nellix endovascular aneurysm sealing system (EVAS) is a valid option for the treatment of infrarenal abdominal aortic aneurysm (AAAs) that has distinctive design comprising two balloon-expandable endoframes, each sorrounded by a polymer-filled endobags. This technique was conceived with the intention of reducing risk of endoleak by filling the aneurysmal lumen excluded by endoprosthesis. However the long-term impact of EVAS on sac remodeling and thrombus modification is still unclear.Our aim was to evaluate the modifications in aneurysmal sac in patients treated by EVAS for AAAs in terms of morphology and thrombus characteristics using MRI at one-year follow-up.

METHOD AND MATERIALS

We enrolled 10 patients EVAS candidates for AAAs. All patients underwent MRI before, 1-week and 1-year after EVAS treatment. We determinated AAA morphological features (diameter, proximal neck, lenght, AAA sectional areas, sac volume, endoleak presence and lumen volume) and thrombus characteristics (thrombus volume and maximal thickness, T1 and T2 signal).

RESULTS

No early or late endoleaks were observed in all patients after EVAS. We observed significant reduction of sac and thrombus volume (mean value:44.5mL Vs 40.9mL and 7.5mL Vs 3.5mL, respectively, p:0.01-0.23). Diameter and thrombus thickness did not change significantly at 1- year follow-up after EVAS (48.5mm vs 47.3mm, 12.4 vs 11.3mm, respectively, $p > .05$ for both). The MRI signal of thrombus showed a reduction of T1 and T2 values (mean difference: -45% and -30%, respectively, p:0.01-0.03) at the 1-year

follow-up.

CONCLUSION

Filling the endobags inside the aneurysmal sac leads to the progressive reduction of thrombus volume and lowering of T1/T2 values, probably due to thrombus organization and squeezing of fluid content into collateral vessels. EVAS could be associated to an acceleration of thrombus remodeling after AAAs treatment

CLINICAL RELEVANCE/APPLICATION

The accelerated thrombus remodeling, in addition to the intrinsic advantages offered by Nellix technology, could further reduce the rates of device-related complications, such as endoleak , endograft migration, component separation and sac enlargement.The positive pressure exerted by two endobags anchored to the endoprosthesis probably facilitate thrombus organization and compaction, by confering more stability to the whole system.

SSA24-04 Remodeling of Aorta After Thoracic Endovascular Aortic Repair for Aortic Dissection

PURPOSE

It is well known that favorable remodeling of the aorta after thoracic endovascular aortic repair (TEVAR) does not occur and leads to enlargement of the distal aorta in some patients with aortic dissection (AD). The objective of this study is to determine the most appropriate timing of TEVAR for AD in terms of remodeling of the aorta.

METHOD AND MATERIALS

Since March 2004 through March 2017, 99 patients with AD underwent TEVAR. Among them, 36 patients who were followed-up with CT over 1 year were included in this study. There were 28 men and 8 women. Mean age was 66 ± 9 years. The diameters of the aorta, the true lumen, and the false lumen were measured at the levels of the most dilated descending aorta (level M) and the diaphragm (level D) on contrast enhanced CT. In addition, the ratio of the diameter measured on CT before TEVAR to that 1 year after TEVAR was calculated in each measurement.

RESULTS

The cut-off interval of 2.5 months between the onset of AD and TEVAR was determined by means of a receiver operating characteristic curve in terms of existence of shrinkage of the aortic diameter at level D on 1-year follow-up CT (AUC:0.724). According to this interval, patients were divided into two groups: patients who underwent TEVAR within 2.5 months of the onset of AD (n=16, group A) and patients who underwent TEVAR over 2.5 months (n=20, group B). At level M, the diameter of the aorta and the false lumen significantly decreased and that of the true lumen significantly increased in both groups ($P<0.01$). At level D, the diameter of true lumen significantly increased and that of the false lumen significantly decreased in both groups ($P<0.01$) although there was no significant difference in the diameter of the aorta. In terms of the diameter ratio, the false lumen shrank more in group A compared to group B at both levels of M ($P=0.017$, CI:0.044-0.424) and D ($P=0.015$, CI:0.078-0.667).

CONCLUSION

To obtain favorable remodeling of the aorta, it seems to be more effective to perform TEVAR within 2.5 months of the onset of AD.

CLINICAL RELEVANCE/APPLICATION

To obtain favorable remodeling of the aorta, it seems to be more effective to perform TEVAR within 2.5 months of the onset of AD.

SSA24-05 Early Intervention for Penetrating Aortic Ulcer Leads to Improved Outcome and Overall Survival

PURPOSE

The natural history of penetrating aortic ulcer (PAU) has been variably described and clear guidelines are lacking. We reviewed our experience with penetrating aortic ulcers in a tertiary referral center.

METHOD AND MATERIALS

Imaging reports from January 2010 – December 2017 were retrospectively searched for the diagnosis of penetrating aortic ulcer.

Imaging reports from January 2010 - December 2017 were retrospectively searched for the diagnosis of penetrating aortic ulcer. Diagnosis was confirmed by review of imaging studies. Patient demographics, presenting symptoms, and anatomic characteristics were collected and analyzed for associations with need for surgical intervention, aortic complication, and overall survival.

RESULTS

One hundred and six patients with PAU were identified. Locations included: 57 (53.8%) aortic arch, 24 (22.6%) descending thoracic, and 25 (23.5%) abdominal aorta. Dissection was present in 12 (11.4%) and acute rupture in 4 (3.8%) cases. At presentation 57 (53.8%) patients were symptomatic. Forty-six (43.8%) patients were evaluated by endovascular interventionalists. Thirteen (12.3%) underwent endovascular repair and 10 (10.4%) had a change in medical management. Long term follow-up was available in 30 patients for a mean 2.3 (2.0) years. Twenty-one (70%; 21/30) demonstrated disease stability or resolution and 9 (30%, 9/30) worsened with 3 undergoing endovascular repair. No PAU ruptured during follow-up. Patient demographics, presenting symptoms, and PAU morphology did not predict disease progression. Referral to a endovascular interventionalist at initial presentation was associated with a 40% decreased likelihood of disease progression (p=0.046) and a 30% survival advantage at LTFU (p=0.037).

CONCLUSION

PAU disease progression occurs in 30% of patients at long-term follow up of 2.3 (2.0) years. All patients identified with PAU on diagnostic imaging should be referred for an evaluation and follow-up, as referral to endovascular interventionalist is associated with improved disease course and overall survival.

CLINICAL RELEVANCE/APPLICATION

Early intervention for penetrating aortic ulcer leads to improved outcome and overall survival

SSA24-06 New 3D-Arterial Analysis Software to Evaluate Carotid Atherosclerotic Plaque in Comparison With CEUS, CTA, and Histological Examination

PURPOSE

To assess the effectiveness of ultrasonographic 3D-Arterial Analysis in characterizing stenosis percentage and vulnerability of carotid plaques as compared with CEUS, CTA and histology results.

METHOD AND MATERIALS

Sixty seven patients were enrolled with the following criteria: (1) asymptomatic stenosis of carotid artery >70% but <100%; or (2) recent transient ischemic attack or ischemic stroke, and ipsilateral carotid stenosis >50%. Eventually all patients underwent endarterectomy and samples were histologically assessed for instability features. 3D-Arterial Analysis provided a colour map to evaluate plaque vulnerability and a 3D volumetric stenosis evaluation. Its diagnostic performance was compared to histological examination for plaque's vulnerability and to CEUS and CTA for stenosis' grading.

RESULTS

Histological examination identified 47 vulnerable plaques with at least one of the following criteria: fibrous cap <200 µm, presence of lipid core, intra-plaque haemorrhage, leukocyte recruitment or angiogenesis. 3D-Arterial Analysis software, CEUS and CTA were able to detect 42, 41 and 41 of these 47 vulnerable plaques respectively, with 89%, 87% and 87% sensitivity and 100% specificity. 3D-Arterial Analysis software and CEUS were able to evaluate stenosis percentage with 88% sensitivity and 100% specificity compared to CTA, identifying 59/60 severe stenosis.

CONCLUSION

3D-Arterial Analysis software and CEUS seem effective tools to assess plaque's vulnerability and stenosis severity, providing useful information for surgery planning.

CLINICAL RELEVANCE/APPLICATION

Multiparametric ultrasound is a safe and effective modality to provide comprehensive information on carotid plaques. Further studies are needed to determine which could be its clinical role.

SSA24-07 EZ-Access: A Novel 3D Printed Groin Puncture Device

Sunday, Nov. 25 11:45AM - 11:55AM Room: S502AB

Participants
Rahmi Oklu, MD,PhD, Phoenix, AZ (*Presenter*) Nothing to Disclose
Hassan Albadawi, MD, Phoenix, AZ (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Exsanguination is the leading cause of death after vascular trauma. Resuscitative endovascular balloon occlusion of the aorta (REBOA) can control torso hemorrhage. However, adoption of this approach specifically by the military has been limited by challenges in achieving femoral artery access in austere combat environments. To address this need, we developed a novel 3D printed minimally invasive device, termed EZ-Access, to enable successful vascular access without the need for ultrasound

guidance or specialized training for use in the field by first responders.

METHOD AND MATERIALS

EZ-Access was modeled using SolidWorks and 3D printed with a methacrylated resin using FormLabs2 printer. The device measured 14x2x1cm with two concave thumb rests on either side of a central plate containing 6 equidistant holes spaced at 0.8cm. The holes were fitted with a variable number of 21-gauge 7cm percutaneous entry needles followed by extensive testing. Multiple trials involved IR staff, residents, college and high school students to test success of accurate access of femoral artery using SimuLab models (Seattle, WA). Trial 1 consisted of 3 needles in alternating holes (n=40). Trial 2 used 6 sequentially placed needles (n=42). The needles within the device were inserted without ultrasound (US) guidance, two fingerbreadths lateral to the pubic symphysis. The device was angled along the groin crease and the needles entered the skin at a 45 degrees. After each puncture, US was used to confirm vessel entry. A control trial was also performed using standard single-entry access needle (n=5) by staff IR. Statistical analysis performed using Prism software (P=0.05).

RESULTS

The control trial demonstrated vessel entry rate of 20%. Using 3 alternating needles, successful vessel entry increased to 40% (p=0.396). With 6 sequential needles, vessel entry success significantly increased to 100% (p<0.001) regardless of operator experience.

CONCLUSION

EZ-Access has demonstrated overwhelming success in obtaining consistent percutaneous vascular access in a simulated clinical scenario independent of the operator's experience without the need for imaging guidance. The device has promising applications in pre-hospital resuscitation.

CLINICAL RELEVANCE/APPLICATION

Access into arterial system can be challenging especially in austere environments; EZ-Access may lead to a higher use of REBOA and improve outcomes.

SSA24-08 Effect of Rosuvastatin and Aspirin Therapy for Abdominal Aortic Atherosclerotic Plaque in Rabbits: A Magnetic Resonance Imaging Study

PURPOSE

To evaluate the therapeutic effect of rosuvastatin, aspirin and two-drug combination on atherosclerotic plaque by conventional magnetic resonance imaging, explore its inhibition of inflammatory cells.

METHOD AND MATERIALS

160 New Zealand rabbits were given endothelial denudation combined with a cholesterol-enriched diet to induce abdominal aortic atherosclerosis. all rabbits were assigned randomly to control group (high fat diet), group A (high fat diet with aspirin), group T(high fat diet with rosuvastatin) and group AT(high fat diet with aspirin as well as rosuvastatin), 40 for each group. Four groups of animals were divided randomly into 1 week , 2 weeks 1month and 2 months subgroup. All rabbits underwent MR scan. Specimens of abdominal aorta were obtained within 24 hours after MR scan, afterwards HE stain and macrophages RAM - 11 ICH staining was performed. Using software CASCADE quantitatively analyse abdominal aorta MRI, to acquire the wall standardized(NWI). Using the software Image-Pro Plus quantitatively analyse the RAM-11 ICH Image. Through compare NWI of group A, T, AT with control group at different time, study the changes of NWI, the number of plaque macrophages after drug treatment.

RESULTS

1) At four time points, the NWI of A, T and AT group is lower than the control group. At 1 week,1 month,2 month, the difference was statistically significant ($P < 0.05$).At 2 weeks, there was no significant difference ($P > 0.05$). 2) At four time points, the arterial intima gradually thickened in the control group over time.1month and 2 months, rendering the appearance of foam cell aggregation, lipid drops calm, disordered arrangement of collagen fiber hyperplasia. At each time point, the degree of arterial intimal thickening in group A,T,AT was less than that in the control group, and the accumulation of foam cells and deposition of lipid droplets were decreased compared with the control group.3)At 2 months,the macrophage of plaque with group A,T,AT were all decreased compared with the control group.

CONCLUSION

1) Rosuvastatin, aspirin and two drug combination can restrain plaque load, reduce inflammatory response. MR can response the inhibition, thus MR can be used in the evaluation of drug therapy. 2)Rosuvastatin combined aspirin can better reduce plaque load, reduce the number of macrophages.

CLINICAL RELEVANCE/APPLICATION

Black blood MR technology can be used to evaluate the effect of drugs on plaque treatment.

SSA24-09 18F-FDG Uptake as a Predictive Factor for Late Aortic Enlargement in Subacute Aortic Dissection

PURPOSE

Purpose: Although previous study demonstrated that greater uptake of 18F fluoro-2-deoxy-D-glucose (FDG) in the dissected aortic wall was significantly associated with an increased risk for adverse aortic events in acute aortic dissection (AD), clinical assessment in subacute aortic dissection remains unexplored. This study was aimed to clarify the relationship of 18F-FDG uptake and late aortic enlargement in medically treated patients with subacute AD.

METHOD AND MATERIALS

Materials and Methods: A total of 16 medically treated patients with subacute AD (age: 69±9, 2 Stanford type and 14 type B) were prospectively enrolled in this study. PET/CT images were acquired 60 minutes after 18F-FDG injection in all patients. All patients underwent 18F-FDG PET/CT between 2 weeks and 4 months from the onset of aortic dissection. In all examinations, 10-mm circular regions of interest were drawn at the site of the dissected aortic wall with maximal focal 18F-FDG uptake. Areas with maximal focal 18F-FDG uptake were visually detected and the maximal standardized uptake value (SUV) was measured. The maximal SUV was divided by the blood-pool SUV, yielding a target-to-background ratio (TBR) for dissected aortic segment.

RESULTS

Results: During a median follow up of 21 (range 12-28) months, surgical repair was required in 4 patients due to aortic enlargement. In these patients, aortic diameter enlarged by more than 10mm compared to that of the onset. There was significant difference in TBR between patients undergoing surgical repair and the other patients (p=0.012). With TBR of 1.8 as cutoff level for the predictor of aortic enlargement, the sensitivity, specificity, and positive and negative predictive value, accuracy, and odds ratio were 75%, 75%, 50%, 90%, 75%, and 9.0, respectively.

CONCLUSION

Conclusion: Greater uptake of 18F-FDG in subacute AD was significantly associated with an increased risk for aortic enlargement. 18F-FDG PET/CT may be useful for predicting the unfavorable aortic enlargement in medically treated patients with subacute AD.

CLINICAL RELEVANCE/APPLICATION

(dealing with 18F-FDG PET/CT) 'Greater uptake of 18F-FDG in subacute aortic dissection was significantly associated with an increased risk for aortic enlargement.'

PURPOSE

The albumin-bilirubin (ALBI) grade is a newly raised objective liver function assessment tool as well as an emerging alternative of the Child-Turcotte-Pugh (CTP) grade in hepatocellular carcinoma (HCC). We aimed to construct ALBI and CTP grades based nomograms as well as develop an artificial neural network (ANN) to compare the prognostic performance of these two grades.

METHOD AND MATERIALS

This multicentric retrospective study included all patients with HCC who underwent TACE monotherapy as initial treatment between January 2008 and December 2016 at four institutions. In the training cohort, independent risk factors associated with overall survival (OS) were identified by univariate and multivariate Cox proportional hazards analyses. The prognostic nomograms and ANN were then established in the training cohort and validated in the two validation cohorts.

RESULTS

Totally, 838 patients (548, 115, and 175 in the training cohort and validation cohorts 1 and 2, respectively) were included. The median OS was 10.4, 15.7, and 9.2 months in the training cohort and validation cohorts 1 and 2, respectively. In the training cohort, independent risk factors were identified as: higher Eastern Cooperative Oncology Group (ECOG) grade, portal vein tumor thrombosis (PVTT), extrahepatic spread (exclude PVTT), higher ALBI/CTP grade, a-fetoprotein level greater than 200 ng/mL, multiple tumors, and tumor size larger than 5 cm. The ALBI and CTP grades based nomograms were then established separately, and showed comparable prognostic performance when assessed externally in two independent validation cohorts (C-index in validation cohort 1: 0.823 vs. 0.802, P =0.417; in validation cohort 2: 0.716 vs. 0.729, P =0.793). ANN showed that ALBI grade had higher importance on survival prediction than CTP grade.

CONCLUSION

The ALBI grade outperforms the CTP grade on survival prediction for HCC patients who undergo TACE. Considering the easy application, the ALBI grade should be regarded as an alternative to CTP grade.

CLINICAL RELEVANCE/APPLICATION

The ALBI grade should be regarded as an alternative to CTP grade about prognostic prediction for HCC underwent TACE.

SSA25-02 Predicting Patient Survival After TACE for HCC Using a Neural Network: A Promising Tool

Sunday, Nov. 25 10:55AM - 11:05AM Room: S503AB

PURPOSE

Transarterial chemoembolization (TACE) is the standard of care for intermediate stage hepatocellular carcinoma (HCC). Nevertheless, even for experienced investigators it can be challenging to decide when to repeat and when to stop TACE-treatment. To objectify treatment decisions, several scoring systems have been developed, e.g. ART, ABCR, and SNACOR. However, the predictive ability was only poor-moderate in several attempts of external validation. Therefore, our aim was to develop a survival prediction model for patients with intermediate stage HCC undergoing TACE using novel machine learning algorithms.

METHOD AND MATERIALS

For this retrospective analysis, we included 792 patients who underwent TACE for HCC at our tertiary referral centre between 01/2005-01/2017. Clinical parameters were acquired from the institutions clinical registry and laboratory system. Radiological response was evaluated in consensus by two board certified radiologists experienced in HCC imaging. Consecutively, we built an artificial neural network, which included all parameters used by the aforementioned clinical risk scoring systems (i.e. ART-, ABCR-, and SNACOR-score): baseline BCLC stage, alpha-fetoprotein level, tumour size and number, as well as change of Child-Pugh stage, AST, and radiological response after the first TACE.

RESULTS

With ten-fold cross validation, the neural network showed a promising performance at predicting one-year survival with an area under the ROC curve of 0.69 and a positive predictive value of 78.6%. This outperforms other established risk stratification scores such as ART, ABCR, and SNACOR.

CONCLUSION

Neural networks could prove superior in predicting patient survival after TACE for HCC compared to other commonly used scoring systems. Inclusion of additional parameters in the prediction model is likely to further increase its performance.

CLINICAL RELEVANCE/APPLICATION

Once established, such novel prediction models could easily be deployed in clinical routine and help in determining optimal patient care.

SSA25-03 Experimental Study on Transarterial Administration of Bevacizumab Combined with Transarterial Chemoembolization in Rats with Hepatocellular Carcinoma

Sunday, Nov. 25 11:05AM - 11:15AM Room: S503AB

PURPOSE

To evaluate the effects of transarterial administration of Bevacizumab (Avastin), an inhibitor of vascular endothelial growth factor (VEGF), combined with transarterial chemoembolization (TACE) to treat hepatocellular carcinoma in rats.

METHOD AND MATERIALS

Subcapsular implantation of a solid Morris hepatoma 3924A (2 mm3) in the liver was carried out in 20 male ACI rats. Animal subjects were assigned to group based on which treatment-drugs were injected into the hepatic artery: group A: TACE (mitomycin C + lipiodol + degradable starch microspheres) + bevacizumab; group B: TACE alone. Tumor volumes of the post-treatment (V2) and pre-treatment tumor (V1) were assessed by magnetic resonance imaging (MRI) and the mean ratio (V2/V1) was calculated. Immunohistochemical expression of MMP-9 and VEGF in the tumor was semi-quantified in all rats.

RESULTS

The rate of tumor implantation reached 100 % in all the rats receiving tumor implantation with Morris hepatoma 3924A. None of the animals died during implantation or interventional therapy. A total of 20 individual HCC tumors were observed with unenhanced MR imaging in the livers of 20 rats (100%) before treatment. After different interventional treatments, intrahepatic metastases developed in one of the 10 rats in group B. The mean value of the volume ratios [V2 (postreatment /V1 (pretreatment] were 1.6649 ± 0.1255 in group A, and 3.0061 ± 0.1910 in group B, respectively. Significant differences of mean volume ratio (V2/V1) were observed between the two groups using an unpaired t test ($P<0.0001$) (Fig.1) (Fig.2). The angiogenesis of tumor was evaluated using anti-VEGF antibodies, and the metastasis of tumor was assessed using anti-MMP-9 antibody. MMP-9 and VEGF were expressed in all specimens. The immunoexpression of these proteins was confirmed by the presence of red cytoplasmic staining in tumor cells. Higher expressions of MMP-9 (4.9 ± 0.199) and VEGF (4.2 ± 0.79) in hepatocellular carcinoma were observed in the group B (TACE alone) than the MMP-9 (1.9 ± 0.733) and VEGF (2.9 ± 0.678) in group A (TACE + Bevacizumab). Statistical significance was calculated using Wilcoxon signed ranked test (both $P<0.0020$) (Tab.1) (Fig3).

CONCLUSION

Transarterial administration of bevacizumab combined with TACE noticeably inhibit the growth of hepatic carcinoma and intrahepatic metastases in rats.

CLINICAL RELEVANCE/APPLICATION

PURPOSE

Lung shunt fraction (LSF) studies using Technetium-99m macro aggregated albumin (Tc-99m-MAA) are routinely performed prior to Yttrium-90 (Y90) radioembolization in all eligible patients regardless of underlying malignancy. This study evaluates the utility of performing Tc-99m-MAA lung shunt fraction studies in patients with hepatocellular carcinoma (HCC) compared to those with non-HCC liver tumors.

METHOD AND MATERIALS

A multi-hospital retrospective analysis of all pre-Y90 Tc-99m-MAA LSF studies between November 2012 to March 2018 was performed. Patient records were evaluated for age, gender, LSF, and underlying malignancy. Tc-99m-MAA studies were evaluated for mean LSF and were compared between HCC and non-HCC cases (p=.05).

RESULTS

A total of 734 Tc-99m-MAA studies were identified among 653 patients. Among these cases 368 (50.1%) involved HCC, 112 (15.3%) colorectal cancer metastatic to liver, 89 (12.1%) neuroendocrine tumor metastatic to liver, 59 (8.0%) cholangiocarcinoma, 27 (3.7%) breast cancer metastatic to liver, and the remaining 79 cases (10.7%) involved other primary malignancies metastatic to liver. The mean LSF of non-HCC cases, 7.4%, was significantly lower than the mean LSF of HCC cases, 11.7% (p=0.0001). There was only one non-HCC case in which a Y-90 radioembolization was not pursued due to high LSF (69.3%), a case of metastatic GIST to liver, in which large scale shunting through the 8 cm mass was grossly apparent on the angiogram. This is compared to at least 37 HCC cases (mean LSF 35.1%) in which LSF was too high to pursue radioembolization.

CONCLUSION

Tc-99m-MAA LSF is low among patients with liver malignancies that are not HCC. This study indicates that pre-Y90 Tc-99m-MAA studies have limited utility in non-HCC liver malignancies.

CLINICAL RELEVANCE/APPLICATION

Patients with non-HCC liver malignancies may only require a consolidated single procedure selective Y-90 radioembolization without prior Tc-99m-MAA nuclear medicine scan.

SSA25-05 Post-Radioembolization Lung Shunt Fraction Assessment of Yttrium-90 Microspheres with Digital Photon Counting PET/CT: Intra-Individual Comparison with Conventional Photomultiplier Tube-Based PET/CT

PURPOSE

The purpose of this study is to assess the clinical feasibility and estimate 90Y microsphere lung shunt fraction (LSF) following radioembolization using both digital photon counting PET detector (dPET) and conventional photomultiplier tube-based PET detector (cPET) technologies and compare to pre-radioembolization 99mTc macro-aggregated albumin (MAA) LSF.

METHOD AND MATERIALS

In a Phase I intra-individual comparison trial, pre-radioembolization 99mTc MAA was performed in 8 patients who were then treated with 90Y glass microspheres for hepatic malignancies/metastases. Investigational 90Y dPET/CT (Vereos, Philips) and cPET/CT (Gemini, Philips) imaging of the lungs and liver was performed in each patient (4 - 50 hrs following radioembolization). Intra-individual comparison of PET image quality and volumetric assessment of intrahepatic radioactivity was performed by a blinded reader panel. 99mTc MAA LSF was routinely calculated using planar scintigraphy. PET estimation of 90Y LSF was performed using MIMVista (MIM Software).

RESULTS

All patients had evaluable MAA and 90Y PET images for qualitative assessment of radioactivity distribution. Qualitatively, dPET enabled more precise localization of 90Y radioactivity when compared with cPET. Quantitatively, 90Y-treated liver volumes were consistently smaller with dPET than cPET (660 +/- 429 mL for dPET and 944 +/- 595 mL for cPET). There were no instances of significant 90Y microspheres shunting outside of the liver or in the lungs. PET estimation of 90Y LSF was consistently and significantly less (dPET was 0.1 +/- 0.2 % and cPET was 0.2 +/- 0.3 %) than MAA LSF (7 +/- 5 %, $P < 0.001$).

CONCLUSION

There remains an unmet clinical need to improve the quantification of 90Y biodistribution following radioembolization. These results demonstrate the feasibility of 90Y LSF assessment using new dPET and cPET approaches that may identify patients with smaller or larger than anticipated LSFs.

CLINICAL RELEVANCE/APPLICATION

Digital PET technologies may enable new quantitative methodologies for 90Y-dosimetry and improve our understanding of vascular shunting in various liver malignancies/metastases.

SSA25-06 Hepatocellular Carcinoma Prognostication Survival Based on Scoring System Developed and Validated on Combined Milieu Intérieur and Milieu Extérieur

PURPOSE

To explore role of routine laboratory parameters in prediction of overall survival (OS) for hepatocellular carcinoma (HCC) treated with transartrerial radioembolization (TARE) and develop/validate a prognostic scoring system.

METHOD AND MATERIALS

With IRB approval, we selected all HCC patients who received TARE and had alpha-fetoprotein (AFP)>100 ng/dl at baseline. Routine labs [neutrophil-lymphocyte (N/L) (inflammatory-immune response), albumin-bilirubin (ALBI) grade (liver function), and AFP (tumor marker)] were measured at baseline and at 1, 3 and 6 month post-TARE Landmarks. Univariate/multivariate analyses were performed to evaluate OS predictability of these parameters. Scoring systems were developed based on baseline imaging (including PVT, metastases, ascites, portal hypertension); baseline labs and labs at respective landmark (including ALBI and AFP). Cohort was divided randomly into two groups: Predicting Group and Validating Group. This scoring was investigated and validated in the predictability of HCC. Using this score, time-dependent receiver operating characteristics (ROC) were evaluated with survival outcomes at each landmark.

RESULTS

345/401, 238/401, and 167/401 patients had laboratory parameters available at the 1, 3, and 6 month Landmarks, respectively. ALBI score and AFP response were significant OS prognosticators at all Landmarks. Laboratory Score [ALBI+(0.3xLnAFP)] was developed to predict OS from these Landmarks in the Predicting Group and was internally validated. For developing and validating groups; at 1-month landmark, 1-year survival was 69% and 71%, at 3-month landmark ($p<0.001$), 1-year survival was 72% and 66%, at 6-month landmark ($p<0.001$), 1-year survival was 78% and 82% respectively ($p<0.001$). Area under ROCs were correlative with significant survival prognostication.

CONCLUSION

Post-therapeutic AFP response and ALBI scores are easily calculable values from routinely performed blood tests. Our proposed Laboratory Score combines post-therapeutic ALBI score with AFP response and is independent of imaging findings. Following TARE, changes in labs can predict survival earlier even in absence of apparent imaging response.

CLINICAL RELEVANCE/APPLICATION

For HCC survival, imaging response is standard but it may take time. As per our study, laboratory values can also surrogate the HCC survival with earlier results and outcomes.

SSA25-07 Prospective Randomized FAST I Trial: Evaluation of Tumor Response of Colorectal Liver Metastases after Transarterial Chemoembolization with Two Different Protocols Using MRI

PURPOSE

To prospectively evaluate therapy response of third-line transarterial chemoembolization (TACE) for colorectal liver metastases with either degradable starch microspheres (DSM) or Lipiodol (cTACE) using regular and diffusion MRI.

METHOD AND MATERIALS

In total, 50 patients (35 males, 15 females, mean 62 years, range 40-79) underwent TACE. They were randomly assigned into two groups: group A receiving DSM and group B receiving Lipiodol as embolization agents. Chemotherapy consisted of a combination of Cisplatin, Irinotecan, Mitomycin. Therapy response was evaluated using MRI with diffusion imaging and unenhanced MRI sequences, which were performed before each of the three TACE cycles to obtain tumor volume and apparent diffusion coefficient (ADC). In addition, contrast-enhanced MRI sequences were performed before the first and after the last TACE cycle. Local tumor response was evaluated using the RECIST criteria and survival data were analyzed using the Kaplan-Meier estimator.

RESULTS

Evaluation using the RECIST 1.1 criteria showed partial response (PR) in 33% of cases, stable disease (SD) in 13% of cases, and progressive disease (PD) in 53% of cases in the cTACE group while the DSM group showed 23% cases of PR, 59% cases of SD, and 18% cases of PD. Over the course of the therapy, the DSM group showed a statistically significant reduction in the average tumor volume ($p=0.006$). A statistically significant difference in tumor response was not found between the cTACE and DSM groups ($p=0.37$). Maximum ADC values after the last MRI session correlated signficantly with therapy response ($p=0.005$), pre-treatment ADC values, however, did not ($p=0.34$). Median survival in the cTACE group was 13 months and 16 months in the DSM group.

CONCLUSION

A statistically significant reduction in tumor volume was found in the DSM group. No significant difference in tumor response was found comparing the Lipiodol and DSM group. Maximum ADC values may be used to assess therapy response after completion of one or more TACE cycles.

CLINICAL RELEVANCE/APPLICATION

Both the Lipiodol and DSM group show similar results with greater tumor volume reduction for the DSM group.

SSA25-08 Liver Transplantation Following Yttrium-90 Radioembolization: A Comprehensive Report of Short and Long-Term Outcomes of a 170-Patient Cohort

ahmed.gabr@northwestern.edu

PURPOSE

To report short and long-term outcomes of liver transplantation (LT) for hepatocellular carcinoma (HCC) patients bridged or downstaged by Y90 radioembolization

METHOD AND MATERIALS

Between 2004 and 2017, 170 HCC patients underwent LT after receiving Y90. Patients were staged using the United Network of Organ Sharing (UNOS) staging system at the times of their Y90 and LT. Early post-operative outcomes were recorded. Recurrence-free survival (RFS) and overall survival (OS) were calculated using Kaplan Meier Method.

RESULTS

170 patients underwent LT after Y90, with a median time to LT of 7.4 months (IQR: 4.4-10.3). Only 1 patient grade 3 albumin (<3 gm/dl) toxicities and 9 patetients had grade 3 bilirubin toxicities could be attributed to Y90.138 patients were successfully bridged to LT (maintained within Milan criteria) while 11 patients were down-staged to Milan criteria. 12 (7%) developed post-operative complications. Three-month mortality rate after LT was 6/170 (3.5%). 75 (44%), 49 (29%) and 46 (27%) patients showed complete, extensive and partial tumor necrosis on explants pathologic assessment. Three, five and ten-year OS rates were 86%, 80%, and 56% respectively. 20 patients developed recurrence, with 3, 5 and 10-year RFS rates of 79%, 67% and 40%. Median RFS was 119 (95%CI: 68-119) months. There were no significant differences in OS or RFS for bridged or downstaged patients. There was significant difference in terms of number of recurrences and RFS between patients who had complete or extensive necrosis vs patients who had partial necrosis (p<0.0001).

CONCLUSION

Y90 can be used as a locoregional therapy that permits bridging or downtaging to LT. LT after Y90 represents a curative treatment for HCC with excellent OS rates comparable to LT for non-malignant causes. Patients who achieved extensive or complete necrosis have better recurrence free survival outcomes.

CLINICAL RELEVANCE/APPLICATION

Y90 has proven to be not only beneficial for HCC patients with bridging or downstaging to LT but also with good tumor response pre-LT and prolonged recurrence free survival post-LT.

SSA25-09 Predicting Treatment Response of Primary and Secondary Lung Neoplasms to Transpulmonay Chemoembolization (TPCE) and Transarterial Chemoperfusion (TACP) Using Diffusion-Weighted MRI (DWI): Value of Pretreatment Apparent Diffusion Coefficient (ADC)

Sunday, Nov. 25 12:05PM - 12:15PM Room: S503AB

T.Vogl@em.uni-frankfurt.de

PURPOSE

To examine predictive value of apparent diffusion coefficients (ADC) derived from diffusion-weighted MR imaging (DWI) in patients with unresectable primary and secondary lung cancer undergoing transpulmonary chemoembolization (TPCE) and transarterial chemoperfusion (TACP) treatment.

METHOD AND MATERIALS

31 patients with 42 lesions (non-small cell lung cancer (NSCLC) n=13; and lung metastases n=18) underwent examination with DWI prior to first treatment and one month thereafter. Lesion diameter and volume were measured at the beginning and end of each treatment cycle (mean 3.1 procedures per patient) in about 4-week intervals between January 2014 and December 2017. Decreases by at least 30% regarding tumor volume were classified as partial response (PR), an increase by 20% or more was defined as progressive disease (PD), while remaining lesions were categorized as stable disease (SD).

RESULTS

The PR group contained 9 lesions (NSCLC n=8; metastasis n=1), mean pretreatment ADC was 1.164 x 10-3 mm2/s, increase in mean ADC after first intervention was 32.9%. The PD group had 14 lesions (NSCLC n=1; metastases n=13), mean pretreatment ADC was 1.418 x 10-3 mm2/s, increase in mean ADC was 5.0%. Difference between ADC changes in the response groups was significant p<0.01). Lesion pretreatment ADC recorded fair diagnostic value for predicting response (AUC 0.774). Applying a threshold ADC increase of 20.71%, response can be predicted with a sensitivity and specificity of 88% and 78%, respectively (AUC 0.838). In primary lung cancer lesions, correlation of ADC changes with changes in tumor diameter and volume of -0.87 and -0.66, respectively. In metastatic lesions, correlation coefficients were -0.18 and -0.35.

CONCLUSION

A correlation was documented between early increases in ADC and tumor size reduction. Furthermore, responding lesions showed lower pretreatment ADC. DWI seems a suitable method for response prediction. The findings correlated better with primary lung cancer than with lung metastases.

CLINICAL RELEVANCE/APPLICATION

DWI provides the interventionalist with information going beyond morphological tumor aspects and response prediction assists in prioritising treatment locations in patients with multiple lesions

PURPOSE

Aim of this study was to evaluate the intermediate-term impact of coronary Computed Tomography (cCT) versus Stress Echocardiography (STE) as a cardiac risk stratification prior to liver transplantation in a consecutive patient population with unknown coronary artery disease (CAD).

METHOD AND MATERIALS

From 2014 to 2017, 139 consecutive patients, who underwent cCT or STE as a part of the institutional liver transplantation evaluation procedure, were enrolled unless they met the predefined exclusion criteria. 67 patients underwent non-enhanced CaSc followed by prospectively ECG-triggered sequential coronary CTA, in addition to the Agatston-Score, we used the CAD-RADS classification for risk assessment. 72 patients were examined by STE. Follow-up information concerning the primary endpoint, consist of cardiac or non-cardiac death and the combined endpoint of cardiac death, myocardial infarction, revascularisation and stroke was obtained from general practitioners, or treating hospitals, respectively.

RESULTS

The mean follow-up period was 569±442 days. During this time, 40 primary endpoints and 7 combined endpoints occurred. There was no significant difference in the incidence of primary endpoints in patients with pos. cCT or STE compared to patients without a pathological finding. In patients with pos. cCT, significantly more combined endpoint were observed than in the control group (p=0.0004). Moreover, the absence of a pathological finding in cCT or STE was shown to exhibit high negative predictive value. On multivariate analysis, Child-Pugh C liver status was the strongest independent predictor for an primary endpoint, with a 5-fold increased risk. While pos. cCT was the strongest independent predictor for an combined entpoint.

CONCLUSION

cCT and STE both provide excellent risk stratification and intermediate-term prognostic value in patients with unknown CAD. cCTA shows promising results in the initial work-up of unselected liver transplantation candicates with perviously unknown CAD. Patients with positive findings in cCT were successfully routed towards revascularization leading to a non-significant difference concerning the primary endpoint combared to patients with neg. cCT (p=0.47).

CLINICAL RELEVANCE/APPLICATION

Different cardiac imaging methods need to be investigated to avoid cardiac complications in patients undergoing liver transplantation, because the prevalence of asymptomatic CAD is relatively high in this population.

SSC01-04 Utilization of Coronary CT Angiography in Private Offices and Hospitals: Reversal of Earlier Trends and Implications for Radiologists

PURPOSE

To assess recent trends in utilization of coronary CT angiography (CCTA), based upon place-of-service and provider specialty.

METHOD AND MATERIALS

The nationwide Medicare Part B Physician/Supplier Procedure Procedure Summary Master Files for 2006-2016 were the data source. CPT-4 codes for CCTA were selected. The files provided procedure volume for each code. Utilization rates per 100,000 Medicare fee-for-service enrollees were then calculated. Medicare's place-of-service codes were used to identify CCTAs performed in private offices, hospital outpatient departments (HOPDs), emergency departments (EDs), and inpatient settings. Physician specialty codes were used to identify CCTAs interpreted by radiologists, cardiologists, and all other physicians as a group. Because these files represent an entire population count, sample statistics are not required.

RESULTS

The overall CCTA utilization rate per 100,000 Medicare enrollees rose abruptly from 99.1 in 2006 to 210.3 in 2007, but then progressively dropped to 107.1 by 2013. However, thereafter it rose each year, reaching 131.0 in 2016. The private office CCTA utilization rate increased abruptly from 70.3 in 2006 to a peak of 150.1 in 2007, but thereafter dropped rapidly to 39.5 in 2016. The HOPD rate rose from 22.9 in 2006 to 46.1 in 2007, then declined to 36.1 by 2010. However, it thereafter increased progressively to 69.8 in 2016. The ED rate increased continually from 0.4 in 2006 to 5.3 in 2016. Among inpatients, the rate was 11.0 in 2007 and remained relatively unchanged through 2013. But in the 3 subsequent years, it increased to 16.4 by 2016. Radiologists' CCTA market share in the 4 venues in 2016 were: offices 44%, HOPDs 62%, EDs 85%, inpatients 66%. Radiologists' overall share had been 32% in 2007 (the peak year), compared with 60% for cardiologists. However, by 2016, radiologists' overall share was 58%, compared with 38% for cardiologists.

CONCLUSION

After years of declining CCTA utilization, the rate is now increasing, primarily in hospital settings. The private office rate has declined sharply. In a noteworthy reversal of another earlier trend, radiologists currently predominate in this procedure.

CLINICAL RELEVANCE/APPLICATION

After years of decline, the frequency of use of CCTA appears to be increasing, especially in hospital settings and among radiologists.

SSC01-05 Radiomics-Based Machine Learning Differentiates Early from Advanced Coronary Lesions: A Proof of Concept

Monday, Nov. 26 11:10AM - 11:20AM Room: S504CD

PURPOSE

Coronary plaques can be classified into the following histological categories: adaptive and pathological intimal thickening (AIT, PIT), fibrous plaque (Fib), early and late fibroatheroma (EFA, LFA) and thin-cap fibroatheroma (TCFA). Advanced atherosclerotic lesions (EFA, LFA, TCFA) carry higher risk versus early plaques (AIT, PIT, Fib). We sought to assess if radiomic analysis of coronary CTA is superior to conventional CTA plaque assessment performed by experts to identify early vs. advanced lesions and to classify plaques into the six histological categories.

METHOD AND MATERIALS

Coronary cross-sections of 95 plaques in 7 ex-vivo hearts were analyzed. Overall, 607 histology slides and coronary CTA cross-sections were co-registered and analyzed in random order. We derived 1015 radiomic features from each CTA plaque cross-section. Principal components accounting for 90% of the variation were derived. A multivariate k-nearest neighbors machine learning (ML) model was built based-on these parameters. We calculated the diagnostic accuracy of the radiomics-ML model and plaque attenuation pattern classification by experts to differentiate early from advanced atherosclerotic plaques and to classify CTA

cross-sections into the six histological categories. We compared the diagnostic accuracies between the models using the McNemar-test.

RESULTS

After excluding sections with heavy calcium (n=32) and no visible atherosclerotic plaque on CTA (n=134), we analyzed 411 cross-sections of which 30.4% (134/441) were advanced atherosclerotic lesions. The radiomics-ML model which included 13 parameters correctly differentiated early from advanced plaques with a diagnostic accuracy of 82.3%, whereas the expert classification had a diagnostic accuracy of 76.0% (p=0.001). Our ML model was able to classify 63.0% of the CTA cross-sections into the six histological categories correctly.

CONCLUSION

Radiomics-based ML outperforms experts to identify advanced atherosclerotic lesions on coronary CTA. However, ML-based classification of coronary plaques into the corresponding six histological categories has moderate accuracy. Further analysis with larger samples size and validation is needed.

CLINICAL RELEVANCE/APPLICATION

Radiomics-based machine learning could increase the diagnostic accuracy of coronary CT angiography to identify gold-standard histological entities.

PURPOSE

The aim of this study is to evaluate the incremental diagnostic value of stress CTPdyn over CCTA in intermediate to high risk patients scheduled for invasive coronary angiography (ICA) plus clinically indicated invasive fractional flow reserve (FFR) for suspected CAD by using a low dose acquisition protocol with last generation of whole-heart single beat CT scanner.

METHOD AND MATERIALS

Consecutive symptomatic patients with intermediate-to-high pre-test probability of CAD and scheduled for clinically indicated ICA+FFR, were prospectively enrolled. All patients underwent rest-CCTA followed by stress-CTP protocol with adenosine and with injection of 0.7 ml/kg of iodixanol 320 as additional test. CCTA and CTP were defined positive for the presence of >= 50% stenosis and for the presence of subendocardial hypoenhancement encompassing >= 25% of transmural myocardial thickness within a specific coronary territory, respectively. At ICA, obstructive CAD was defined by the presence of >= 50% stenosis and hemodynamically significant CAD was defined by the presence of > 50% stenosis on left main coronary artery, severe (> 80%) or occlusive stenosis or FFR < 0.80. The additive value of CTP versus CCTA alone to rule out the presence of hemodynamically relevant stenosis was assessed on a per-vessel basis.

RESULTS

Forty-eight patients [mean age: 65 ± 8 years, male: 35 (73%)] were included in our study. Obstructive CAD was found in 38% (54/144) of vessels and in 73% (35/48) of patients. Hemodynamically significant CAD was present in 23% (36/144) of vessel and in 54% (26/48) of patients. In a vessel-based model, CCTA alone and CCTA+CTPdyn showed a sensitivity, specificity, negative predictive value, positive predictive value and diagnostic accuracy of 92%, 64%, 96%, 46%, 71% and 89%, 89%, 96%, 76%, 89%, respectively. CCTA+CTPdyn showed a significant improvement in specificity (p: <0.001), positive predictive value (p: 0.002) and diagnostic accuracy (p: <0.001) to rule out haemodynamically significant CAD as compared to CCTA alone. The mean radiation exposure due to CTPdyn alone is 5.13 ± 1.51 mSv.

CONCLUSION

In patients with intermediate-to-high pre-test likelihood of CAD, low dose dynamic CTP had incremental value over CCTA alone to diagnose the presence of hemodynamically significant CAD.

CLINICAL RELEVANCE/APPLICATION

Combination of CTP an CCTA can improve diagnosis of hemodynamically significant CAD.

SSC01-07 Triple-Rule-Out CT Angiography in Low-intermediate and High Risk Patients with Acute Chest Pain: Impact on Patient Management

PURPOSE

To investigate the impact of triple-rule-out cardiac CT angiography (TRO-CTA) on patient management in patients presenting with chest pain to the emergency department (ED) compared to standard of care (SOC) work-up.

METHOD AND MATERIALS

In this IRB-approved, HIPAA-compliant study we analyzed data of 2156 patients who presented to the ED with chest pain. Patients were divided into two groups according to their cardiovascular risk: low-intermediate risk (<=1 risk factor regardless of body-mass-index [BMI]) and high risk (>=2 risk factors and BMI >=30kg/m2 or >=4 risk factors regardless of BMI). Patients received either TRO-CTA as an initial test or SOC without initial CTA. ED length of stay, downstream utilization of additional tests, and hospital costs were compared between both groups.

RESULTS

515 patients were assigned to the high-risk group (TRO-CTA, n=274; SOC, n=241) and 1610 to the low-intermediate risk group (TRO-CTA, n=837; SOC, n=773). No significant differences between groups and corresponding treatment arms were observed for age, gender, or race. The rate of diagnosis of coronary artery disease (CAD), pulmonary embolism (PE), or aortic dissection (AD) was significantly higher in the TRO-CTA vs. the SOC arm for the low-intermediate risk group (all $p<0.05$). Median ED wait time (5.0 vs. 7.0hrs, $p<0.001$), median total length of hospital stay (48.0 vs. 72.0hrs, $p<0.001$), additional downstream testing, rate of invasive coronary angiography (11.6% vs. 38.7%, $p<0.001$), and total costs (9.184$ vs. 17.253$, $p<0.001$) were significantly lower in the TRO-CTA vs. the SOC arm. No significant difference in the diagnosis of CAD, PE, or AD was found between TRO-CTA vs. SOC in the high-risk group with significant lower median ED waiting time (4.0 vs. 8.0hrs, $p<0.001$), median total length of hospital stay (48.0 vs. 72.0hrs, $p<0.001$), additional downstream testing, invasive coronary angiography (16.4% vs. 34.0%, $p<0.001$), and total costs ($10,532 vs. $21,518, $p<0.001$) in the TRO-CTA vs. the SOC arm.

CONCLUSION

TRO-CTA as an initial imaging test in ED patients presenting with acute chest pain was associated with shorter ED and hospital length of stay, lower utilization of downstream testing, and lower total cost both for the episode of care and overall.

CLINICAL RELEVANCE/APPLICATION

TRO-CTA is a robust imaging modality with lower resource use and lower cost in the work-up of patients presenting to the ED with chest pain regardless of their a-priori risk.

SSC01-08 Prognostic Role of Adenosine Stress Cardiac Magnetic Resonance Compared to CCTA in the Long-Term Outcome of Heart Disease Patient

Monday, Nov. 26 11:40AM - 11:50AM Room: S504CD

PURPOSE

Coronary heart disease is still the leading cause of death and the need for a prognostic assessment of CAD patients is continuously increasing. With this regard, the anatomic and morphological approach is not completely satisfying in the CAD definition. The purpose of our study was assessing the prognostic role of Adenosine Stress Cardiac Magnetic Resonance compared to Computed Tomography Angiography (CTA) in the outcome of the heart patient

METHOD AND MATERIALS

55 patients with previous PTCA-stenting who underwent CTA examination and CMR with adenosine were included in our study. A 5-year follow-up was carried out to evaluate the clinical evolution of these patients

RESULTS

Nine patients showed negative CTA and CMR under stress, with reported well-being in the 5-year follow-up. 78% of the remaining patients showed stent filling defects in the CTA examination; among these, 86% showed also perfusion defect in the CMR, associated to major cardiovascular symptoms referred in the follow-up, while the remaining 14% were negative for perfusion CMR and for symptoms.22% of patients who showed perfusion alterations in CMR, although in absence of stent apparent filling defects in CTA examination, reported acute myocardial infarction treated with re-stenting. 5 patients out of 18 with positive LGE images developed MACE (arrhythmias, cardiac death).

CONCLUSION

Our experience shows how, despite a CTA examination positive for the presence of moderate stenosis, a negative Adenosine Stress CMR represents a positive prognostic factor for the patient outcome. On the other hand, also with a negative CTA, the positivity of Adenosine Stress CMR is strongly associated with a high probability of developing a cardiovascular accident and constitutes a negative prognostic factor

CLINICAL RELEVANCE/APPLICATION

Our study demonstrates the prevalent role of Stress CMR in comparison to Computed Tomography as a predictive prognostic factor in the outcome of heart patient

SSC01-09 Additional Diagnostic Value of CT Perfusion Over Coronary CT Angiography in Stented Patients with Suspected In-Stent Restenosis or Coronary Artery Disease Progression: ADVANTAGE Study - Preliminary Results

Monday, Nov. 26 11:50AM - 12:00PM Room: S504CD

PURPOSE

Aim of the study is to assess the diagnostic performance of CCTA alone, CTP alone and CCTA plus CTP performed with the latest scanner generation that combine a whole-heart coverage with high spatial and temporal resolution, by using invasive coronary angiography (ICA) as standard of reference.

METHOD AND MATERIALS

A cohort of consecutive patients referred for a clinically ICA for suspicion of ISR or progression of native CAD were enrolled. The feasibility of CCTA, CTP and the combined evaluation CCTA plus CTP were calculated in a stent-based, territory-based and patient-based analysis. Sensitivity, specificity, positive predictive value, negative predictive value and diagnostic accuracy of CCTA, CTP, combined evaluation CCTA-CTP vs. ICA in a stent-based, territory-based and patient-based analysis. Radiation exposure of CCTA, CTP and ICA was recorded.

RESULTS

Ninety-eight patients were enrolled (83 male, mean age 64 ± 9 years-old). CTP feasibility was significantly higher than CCTA feasibility in a stent-based, territory-based and patient based analysis (97% vs. 87%, p=0.001; 98% vs. 92%, p=0.001; 97% vs. 70%, p<0.0001, respectively). The feasibility of the combined evaluation CCTA-CTP was significantly higher than CCTA feasibility in a stent-based, territory-based and patient based analysis (96% vs. 87%, p=0.001; 99% vs. 92%, p<0.001; 100% vs. 70%, p<0.0001, respectively). The diagnostic accuracy of CCTA was 81%, 85% and 79%, in a stent-based, territory-based and patient based analysis, respectively; the diagnostic accuracy of CTP was 90%, 93% and 84%, respectively; the diagnostic accuracy of combined CCTA-CTP was 85%, 90% and 83%, respectively; the diagnostic accuracy of concordant CCTA-CTP was 95% and 92% in a territory and patient-based analysis, respectively. The diagnostic accuracy of CTP was higher than that of CCTA in a stent-based (p=0.001) and territory-based (p<0.0001) analysis. The mean effective dose of the entire CT assessment (CCTA-CTP) was 2.76 ± 2.32 mSv.

CONCLUSION

The CTP assessment appears as more feasible and more accurate than the anatomical evaluation alone by CCTA in patients with coronary stents. When results of CCTA and CTP are concordant, the diagnostic accuracy of the combined evaluation is very high and associated with very low radiation exposure.

CLINICAL RELEVANCE/APPLICATION

Evaluation with cardiac CT of both anatomy and perfusion

mishida@clin.medic.mie-u.ac.jp

PURPOSE

Radio-water PET is the most accurate method in quantifying myocardial blood flow (MBF). Model-based analysis of perfusion MRI with corrections of blood saturation and flow-dependent alteration in extraction fraction of gadolinium contrast medium may permit quantification of absolute MBF. The purpose of this study was to determine the accuracy of MR measurements of rest and stress MBF at 3.0T by using radio-water PET as a reference.

METHOD AND MATERIALS

Twenty-nine patients with suspected coronary artery disease underwent MRI including stress and rest perfusion MRI and LGE MRI at 3.0T and radio-water PET. ATP stress and rest perfusion MRI were performed with injections of 0.03mmol/kg of Gd-DOTA. Dual bolus method was used to correct blood saturation. Patlak plot method was employed in quantifying MBF. Myocardial unidirectional influx constant (K1) was determined from blood input and myocardial output functions in 16 myocardial segments. The extraction fraction of Gd-DOTA (E) was determined using K1 and PET-derived MBF (MBFPET) for the first 15 patients. For validation, MRI-derived absolute MBF (MBFMRI) was calculated using the relation between E and MBF for the remaining 14 patients and compared with MBFPET. The segments including myocardial infarction were excluded from the analysis.

RESULTS

In the first 15 patients, K1 by perfusion MRI was 0.60±0.21 ml/min/g at rest and 1.07±0.37 ml/min/g during stress, while MBFPET was 1.15±0.35 ml/min/g at rest and 3.08±0.81 ml/min/g during stress. The relationship between E and MBF was E=1-exp(-(0.24xMBF+0.63)/MBF). In the remaining 14 patients, MBFMRI at rest and during stress were 1.24±1.16 ml/min/g and 2.63±1.48 ml/min/g, while MBFPET at rest and during stress were 1.17±0.61 ml/min/g and 2.69±0.70 ml/min/g, respectively. MBFMRI showed a good linear correlation with MBFPET ($r=0.71$, $p<0.001$). The measurement bias in measuring MBF between MRI and PET was 0.01±1.06ml/min/g.

CONCLUSION

Model-based analysis of perfusion MRI at 3.0T with corrections of blood saturation and flow-dependent alteration of extraction of gadolinium contrast medium allows for accurate quantification of MBF both at rest and during ATP stress.

CLINICAL RELEVANCE/APPLICATION

Accurate quantification of myocardial blood flow by using perfusion MRI may permit objective assessment of myocardial ischemia and early detection of high risk patients in the routine cardiac MRI.

SSC02-02 Oxygenation-Sensitive Cardiovascular Magnetic Resonance for Differentiation of Reversible and Irreversible Myocardial Damage by Evaluation of the Balance between Supply/Demand in Myocardial Oxygenation after ST-Segment-Elevation Myocardial Infarct

Monday, Nov. 26 10:40AM - 10:50AM Room: S502AB

Participants
Binghua Chen, Shanghai, China (*Presenter*) Nothing to Disclose
Lian-Ming Wu, Shanghai, China (*Abstract Co-Author*) Nothing to Disclose

chenbinghua0311@163.com

PURPOSE

T2* BOLD imaging is a quantitative magnetic resonance imaging(MRI) technique allowing for evaluation of the balance between supply/demand in myocardial oxygenation and myocardial hemorrhage. We sought to investigate the ability of T2* BOLD imaging to differentiate reversible and irreversible myocardial injury as well as the time course of myocardial oxygenation after reperfusion in patients with ST-segment elevation myocardial infarction (STEMI).

METHOD AND MATERIALS

Twenty two patients(age, 60±11 years;77.27% male)with STEMI underwent cardiac MRI on four occasions: at 1 day, 3 days, 7 days, and 30 days after (percutaneous coronary intervention)PCI. T2* BOLD MRI was performed on a 3T scanner to assess myocardial oxygenation in myocardial infarcted regions with or without intramyocardial hemorrhage (IMH), salvaged myocardium, remote myocardium and normal myocardium.

RESULTS

T2* BOLD value in myocardial infarction(MI) with IMH was lowest(9.77±3.29ms), while that of the salvaged zone was the highest(33.97±3.42ms). Hyperemia induced by inflammation may increase blood flow in the salvaged area. T2* BOLD value in salvaged myocardium demonstrated a unimodal temporal pattern from 1 day(37.91±2.23ms) to 30 days(30.68±1.59ms).

CONCLUSION

T2* BOLD MRI performed in post-STEMI patients allows for accurate evaluation of myocardial damage severity, and can discriminate between reversible and irreversible myocardial injury. The increased T2* BOLD values may imply the pathophysiological mechanism of salvaged myocardium. T2* BOLD could represent a more accurate alternative without contrast to late gadolinium enhancement (LGE) imaging in acute STEMI patients.

CLINICAL RELEVANCE/APPLICATION

BOLD MRI could evaluate the balance between supply/demand in myocardial oxygenation and myocardial damage severity, and discriminate between reversible and irreversible myocardial injury and is recommended in the initial evaluation of STEMI patients.

SSC02-03 Intra-Myocardial Hemorrhage and Microvascular Obstruction After Acute Re-Perfused Myocardial Infarction: Are They Really Two Different Complications?

Monday, Nov. 26 10:50AM - 11:00AM Room: S502AB

bordonaroveronica@gmail.com

PURPOSE

To evaluate the performance of T2* mapping for intra-myocardial hemorrhage (IMH) detection in acute re-perfused myocardial infarction and to demonstrate in vivo the pathophysiological coincidence of microvascular obstruction (MVO) and intra-myocardial hemorrhage (IMH) at the level of the infarcted zone.

METHOD AND MATERIALS

74 consecutive Patients (Pts) after primary percutaneous intervention for first acute myocardial infarction (AMI) underwent cardiovascular MR (CMR) within 1 week after treatment, using a standard protocol (T2 3IR-FSE, cine-SSFP, rest FGRET and 2D IR-FGRE). Before gadolinium administration, we performed T2* mapping at the level of the infarct zone. T2* images were analyzed with a dedicated software (Reportcard 4.0, GE Medical Systems), considering a T2* value <=20 ms as positive for IHM. First-pass perfusion images were acquired during administration of different Gadolinium chelates at a standard dose of 0.1 mmol/kg; early and late gadolinium enhancement (EGE and LGE) were obtained at 2-3 and 12-15 minutes after contrast injection, respectively.

RESULTS

On the basis of post-Gadolinium sequences, MVO in the infarct area was demonstrated in 34 Pts at the first pass perfusion images, in 29 Pts at EGE and in 26 Pts in LGE images.A focal IMH was identified in 13/74 Pts at T2 3IR-FSE images, while on the basis of T2* mapping IMH was detected in 28/74 Pts.We found that IMH coincided with the area of MVO: all 13 Pts with IMH at T2 3IR-FSE images showed MVO at first pass perfusion and/or at EGE and LGE; all 28 Pts positive for IMH at T2* mapping showed MVO at EGE, while only 2 Pts did not show MVO at LGE.

CONCLUSION

T2* imaging should be the preferred CMR method for assessment of IMH because its higher sensitivity than conventional T2 images. Reperfusion IMH is closely associated with the presence of MVO and they represent patho-physiologically the same complication of the ischemia-reperfusion injury.

CLINICAL RELEVANCE/APPLICATION

We demonstrated that MVO and IMH represent the same complication in re-perfused AMI. T2* mapping (better than T2) can be used to assess MVO also in Pts not suitable for gadolinium administration.

SSC02-04 Intramyocardial Hemorrhage May Not Change from 48 Hours to 7days While Myocardial Ischemia and Myocardial Edema Decrease After Reperfusion: A Rat Study at 7T

Monday, Nov. 26 11:00AM - 11:10AM Room: S502AB

PURPOSE

To study the change of intramyocardial hemorrhage(IMH), myocardial edema(ME) and myocardial ischemia(MI) in reperfused myocardial ischemic rat from 48h to 7d in a 7.0T MR scanner.

METHOD AND MATERIALS

Nine rats (SD, 250-300g, male) with 60min myocardial ischemia followed by 48h and 7d were investigated. The myocardial ischemia was induced by occluding the proximal left anterior descending coronary artery, which was then released for reperfusion. The T2*-mapping and T2-mapping pulse sequences (T2-mapping: TR/TE=1500ms/10,20,30 ms, MTX=192×192, FOV=50×50mm, slice thickness=1.5mm. T2*-mapping: TR/TE=1000ms/3.5,7,10.5,14,17.5,21,24.5,28,31.5 ms, FA (Flip angle)=30°, MTX=192×192, FOV=50×50mm, slice thickness=1.5mm) were implemented and optimized on a 7.0T MR system (BRUKER BIOSPEC 70/30, Germany). Images were acquired on the short axis slices during mid-diastolic phase in each end-inspiratory period using both ECG and respiratory gating systems. After the acquisition of T2*-mapping and T2-mapping images, Late gadolinium enhancement (LGE) imaging was performed by FISP(TR/TE=5.2ms/1.8ms, FA=25°, MTX=256×256, FOV=50×50mm, slice thickness=1.5mm) to evaluate the extent of myocardial ischemia after an injection of gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA, Magnevist, Bayer Health Care Pharmaceuticals) at a dose of 0.15 mmol/kg. The T2*-maps and T2-maps were calculated using a custom-made software. The areas of edema regions were defined by high T2 values (> mean ± 2SD in remote areas) on T2 maps. The areas of hemorrhage were identified as a hypointense core within a hyperintense territory on T2* maps. All areas were expressed as a percentage of the whole myocardial tissue of left ventricle.

RESULTS

The area of ME and MI decreased from 48h (31.2±7.9%; 21.9±10.2%) to 7d (23.6±3.8%, $p<0.01$; 10.8±6.6%, $p<0.01$). However, they were not significant different between the area of IMH at 48h (4.8±3.3%) and 7d (5.1±3.4%, $p>0.05$).

CONCLUSION

The area of ME and MI decreased, which may indicate the self-healing of myocardial edema and myocardial ischemia after reperfusion. However, intramyocardial hemorrhage, caused by reperfusion injury, would not recover in this duration.

CLINICAL RELEVANCE/APPLICATION

Reperfusion will decrease myocardial ischemia and myocardial edema, but also cause sustained intramyocardial hemorrhage, which should be recommended as an important risk point for percutaneous coronary intervention of myocardial ischemic patients.

SSC02-05 Larger Myocardial Ischemia May Cause Larger Intramyocardial Hemorrhage and Smaller Area at Risk in Acute Reperfused Myocardial Ischemic Rats

Monday, Nov. 26 11:10AM - 11:20AM Room: S502AB

PURPOSE

To study the correlations between myocardial infarction and intramyocardial hemorrhage, area at risk in reperfused myocardial ischemic rats with a comprehensive method on 7.0T MR.

METHOD AND MATERIALS

Eleven rats (SD, 250-300g, male) with 60min myocardial ischemia followed by 48hours reperfusion were investigated. The different degrees of myocardial ischemia were induced by occluding the different section of proximal left anterior descending coronary artery. The T2*-mapping and T2-mapping pulse sequences (T2-mapping: TR/TE=1500ms/10,20,30 ms. T2*-mapping: TR/TE=1000ms/3.5,7,10.5,14,17.5,21,24.5,28,31.5 ms, FA (Flip angle)=30°) were implemented and optimized on a 7.0T MR system (BRUKER BIOSPEC 70/30, Germany). Images were acquired on the short axis slices during mid-diastolic phase in each end-inspiratory period using both ECG and respiratory gating systems. After the acquisition of T2*-mapping and T2-mapping images, Late gadolinium enhancement (LGE) imaging was performed by FISP(TR/TE=5.2ms/1.8ms, FA=25°) to evaluate the extent of myocardial ischemia after an injection of gadolinium diethylenetriamine pentaacetic acid (Gd-DTPA) at a dose of 0.15 mmol/kg. The T2*-maps and T2-maps were calculated using a custom-made software. Area at risk were defined as the difference between edema areas with high T2 values(> mean ± 2SD in remote normal tissue areas) in T2 maps and positive enhanced area in LGE images. The areas of hemorrhage were identified as a hypointense core within a hyperintense territory on T2* maps. All areas were expressed as a percentage of the whole myocardial tissue of left ventricle.

RESULTS

Myocardial ischemia ranged from 9.5% to 47% (22.7±10.4%), intramyocardial hemorrhage ranged from 1.25% to 17% (5.3±4.5%), area at risk ranged from 2.8% to 15.2% (8.4±3.9%). There was a significant positive correlation between myocardial ischemia and intramyocardial hemorrhage ($r=0.85$, $P<0.01$), while a negtive correlation was found between myocardial ischemia and area at risk ($r=0.77$, $P<0.01$).

CONCLUSION

Larger myocardial ischemia may cause larger intramyocardial hemorrhage and smaller area at risk in 48h reperfused myocardial ischemic rats.

CLINICAL RELEVANCE/APPLICATION

The prognosis of intramyocardial hemorrhage and area at risk could be made by the area of reperfused myocardial ischemia, which should be recommended as a critical index before percutaneous coronary intervention of myocardial ischemic patients.

SSC02-06 Fully Automated Analysis of LGE MRI in Post-Infarct Patients Using Convolutional Neural Networks: Simultaneous Segmentation of Ventricular Myocardium and Myocardial Infarction

Monday, Nov. 26 11:20AM - 11:30AM Room: S502AB

PURPOSE

To investigate the feasibility of deep-learning convolutional neural network (CNN) image segmentation for fully automated analysis of late gadolinium enhanced (LGE) MRI in post-infarct patients.

METHOD AND MATERIALS

In 180 consecutive post-infarct patients LGE MRI was acquired prior to ICD implantation. An inversion-recovery 3D turbo-field echo sequence was used with parallel imaging, in one or two breath-holds and reconstructed into 20-24 levels in the short-axis view with a typical image resolution of 1.56×1.56×5 mm. For reference, an experienced observer manually traced the endocardial and epicardial contours and assessed the region of myocardial scar using the Full Width Half Maximum (FWHM) method, followed by visual correction, if needed. The cohort was randomly divided into a training set of 150 (3,606 images) and a testing set of 30 subjects (726 images). The training images were augmented into a total of 144,240 images by applying moderate rotation (-15 to 15 degree) and scaling (0.8 to 1.25). The U-Net CNN architecture was adopted to learn the manual segmentation from the training set, using cross entropy as the metric, with a learning rate of 10-4, in 50 epochs, initialized from a previously trained network for cine MR segmentation. The trained network was evaluated on the 30 independent testing subjects. We evaluated: (1) the accuracy of endocardial and epicardial contour in terms of average perpendicular distance (APD) in pixels, and (2) the accuracy of identified myocardial scar size per subject.

RESULTS

On the independent training set, the APD was 1.10±0.39 and 1.09±0.29 pixels for the endocardial and epicardial contours, respectively. The identified scar size per subject was not significantly different between the CNN and the human observer: 29.1±21.3 g vs. 31.7±20.8 g ($p=0.2$). The processing time for CNN based segmentation was less than 0.2 seconds per subject.

CONCLUSION

Deep-learning CNN shows great promise in the challenging segmentation problem of automated LGE MRI quantification in post-infarct patients, by simultaneously identifying the left ventricle and myocardial scar in a fully automated manner.

CLINICAL RELEVANCE/APPLICATION

With further validation, the developed deep-learning CNN can be used to rapidly identify and quantify the myocardial scar from LGE MRI, avoiding time-consuming and user-dependent scar assessment and contour tracing.

SSC02-07 Myocardial Edema and Necrosis after ST-Segment Elevation Myocardial Infarction by T2-Weighted and Late Gadolinium Enhancement MR Imaging: A Meta-Analysis

benjamin.kendziora@charite.de

PURPOSE

To analyze existing data on the extent of myocardial edema and necrosis measured by T2-weighted and late gadolinium enhancement (LGE) magnetic resonance (MR) imaging after ST-segment elevation myocardial infarction (STEMI).

METHOD AND MATERIALS

We searched MEDLINE, EMBASE, and ISI Web of Science for patient studies reporting the extent of myocardial edema and necrosis measured by T2-weighted and LGE MR imaging after STEMI. All information on patient demographics, treatment features, and imaging techniques reported by included studies were extracted. Multiple imputation was used for missing data and mixed-effects models to identify significant predictors of edema and necrosis. Follow-up data were used to evaluate the further temporal evolution of edema and necrosis.

RESULTS

Forty-four studies with 5028 patients were included. Overall, edema area measured using T2-weighted MR imaging during the first week after STEMI was 33.8% of left ventricular (LV) myocardium (confidence interval [CI]: 31.9, 36.5), necrosis area measured using LGE MR imaging was 18.1% of LV myocardium (CI: 14.7, 21.4), and the proportion of edematous myocardium without necrosis was 42.0% (CI: 34.6, 49.4). Each hour of delay in revascularization increased necrosis by 3.6% of LV myocardium (95% CI: 1.1, 6.0; P = .013) and decreased the proportion of edematous myocardium without necrosis by 12.5% (95% CI: 6.9, 18.1; P = .002), while edema was not significantly affected. Other significant predictors were the degree of obstruction of the culprit artery before revascularization and the applied method for interpreting MR images. Within 6 months after STEMI, edema disappeared, while necrosis decreased only slightly but significantly.

CONCLUSION

This meta-analysis indicates that myocardial edema on T2-weighted MR imaging delineates the area at risk after STEMI and can be used to quantify the proportion of reversibly injured myocardium, commonly defined as myocardial salvage index, when combined with LGE MR imaging of necrotic myocardium.

CLINICAL RELEVANCE/APPLICATION

Quantification of the proportion of reversibly injured, salvaged myocardium after STEMI by T2-weighted and LGE MR imaging allows evaluation of therapeutic efficiency.

SSC02-08 Detection of Occult Myocardial Scars with Cardiovascular Magnetic Resonance Imaging in Patients with Asymptomatic Type 2 Diabetes Mellitus: The ACCREDIT Study

PURPOSE

To determine the prevalence of occult myocardial scars (OMS) on contrast-enhanced cardiovascular magnetic resonance imaging (CMR) in asymptomatic patients with type 2 diabetes mellitus (DM) and to assess the relationship between the occurrence of OMS detected with CMR and coronary atherosclerosis observed with contrast-enhanced coronary computed tomography angiography (CCTA).

METHOD AND MATERIALS

This multi-center, prospective, open-label study included asymptomatic patients with type 2 DM and at least two identified cardiac risk factors, scheduled to undergo CMR and CCTA procedures. CMR and CCTA were performed with gadoterate meglumine (Dotarem®, Guerbet) and iobitridol (Xenetix®, Guerbet), respectively. The prevalence of OMS was calculated on CMR. For each main coronary artery, stenosis degree and plaque characteristics were assessed on CCTA. For each myocardial segment with OMS, the corresponding infarct-related artery (IRA) was identified according to the American Heart Association recommendations. The

characteristics of the plaques located in IRA were compared to those located in non-IRA.

RESULTS

Among the 348 patients included (mean (±SD) age: 60.2±6.5 years; male: 60.9%; mean BMI: 25.4±3.1 kg/m2), 322 patients completed both CMR and CCTA procedures. At least one OMS was detected by CMR in 23 patients (7.1%). CCTA showed a significant stenosis (>50% diameter reduction) or occlusion for 13 (56.5%) of the 23 patients with OMS and for 67 (22.4%) of the 299 patients without OMS. Sixty-two IRA plaques and 52 non-IRA plaques were identified with CCTA in patients with OMS. In IRA, 16.1% plaques were non-calcified, 22.6% mixed and 61.3% calcified while in the non-IRA, 30.8% were non-calcified, 17.3% mixed and 51.9% calcified. No differences in calcification status were demonstrated between IRA and non-IRA plaques (p=0.175, Chi²).

CONCLUSION

OMS were identified with CMR in 7.1% of asymptomatic patients with type 2 DM. No significant difference was demonstrated in plaque characteristics between IRA and non-IRA in patients with OMS. Further investigations are still required to determine whether the occurrence of OMS is related to atherosclerosis detected with CCTA.

CLINICAL RELEVANCE/APPLICATION

CT and MRI screening in diabetes patients without chest pain can provide the information of occult myocardial infarction and its relationship to coronary arterial disease.

SSC02-09 Multi-Parametric Rest and Dobutamine Stress Cardiovascular Magnetic Resonance in Assessment of Myocardial Viability: Could Feature Tracking Strain Analysis Add Value?

PURPOSE

To evaluate the diagnostic accuracy of multi-parametric CMR in assessment of myocardial viability in chronic ischemic patients using 4 different techniques; delayed gadolinium enhancement(DGE) as gold standard for detection of scar burden, CMR feature tracking(CMR-FT) at rest and with low dose dobutamine(LDD), visual assessment of myocardial contractility with LDD and LV end-diastolic wall thickness(EDWT)

METHOD AND MATERIALS

15 patients(53±12years) &10 controls(38±11years) were prospectively enrolled. All subjects had CMR exams on 1.5T scanner. A LDD IV infusion was administrated in 2 stages, 3 minutes each, with a dose of 5 µg/kg/min that is increased to 10 µg/kg/min in 2nd stage. LV was divided into 16 segments and FT parameters were derived from SSFP Cine images using dedicated software. Viable myocardium was defined as a dobutamine induced increase in resting FT values of >20 % & systolic wall thickening of >=2 mm by visual assessment. A segment with no or <=50 % fibrosis on DGE & EDWT of >5 mm was defined as viable

RESULTS

240 segments were analyzed for patients at rest & with LDD &160 segments for controls at rest. 44 segments were non-viable based on DGE &196 were viable. Both peak global circumferential(Ecc) & radial(Err) strains were significantly impaired in ischemic patients compared to healthy(-12.84±7.72 vs -19.63±7.08,P<0.0001 & 22.07±15.19 vs 30.90±18.59,P=0.0039)respectively. With segmental Ecc, 50 segments were identified as non-viable & 190 as viable(sensitivity 72%,specificity 91% &diagnostic accuracy 87%).With segmental Err, 49 segments were identified as non-viable & 191 as viable(sensitivity 54%,specificity 87% & diagnostic accuracy 81%).By visual assessment of myocardial contractility with LDD, 43 segments were identified as non-viable & 197 as viable(sensitivity 70%,specificity 86% & diagnostic accuracy 88%).Based on EDWT assessment, 41 segments were identified as non-viable & 199 as viable(sensitivity 50%,specificity 90%& diagnostic accuracy 83%)

CONCLUSION

Quantitative assessment of Ecc & Err with FT, along with EDWT & qualitative visual assessment of myocardial contractility at rest & with LDD may improve diagnostic accuracy of non-viable segments with moderate sensitivity & high specificity

CLINICAL RELEVANCE/APPLICATION

FT and EDWT are non-contrast parameters that could be of particular importance in determining viability in patients with impaired glomerular filtration rate or patients with known hypersensitivity to contrast agents

sohn87@gmail.com

PURPOSE

A large number of patients undergo annual lung cancer screening with low-dose chest CT. The CT data contains significant information about health of the patient, beyond simple lung cancer status. The National Lung Cancer Screening (NLST) database provides a large dataset with correlated clinical metadata, which can be used to train machine learning algorithms to extract as much useful health information as possible. The aim of the study is to develop and validate a 3D convolutional neural network algorithm on these CT studies to predict the likelihood of various major diseases: diabetes, heart disease, COPD, and stroke.

METHOD AND MATERIALS

We extracted random samples of 16,780 scans from NLST. Data preprocessing consisted of isotropic resolution resizing and standardization to 350 x 350 x 35 pixel size. Data was augmented with random rotations between -15 and 15 degrees. The processed samples were passed through a 3D convolutional neural network (CNN) with architecture loosely inspired by the VGG-Net. Modifications included generalization to 3D dataset, more gradual pooling across the z-axis, and use of batch normalization. Stochastic gradient descent optimizer and sparse categorical crossentropy loss function were utilized. Final results were gathered using a separate testing set extracted from the NLST dataset. Error analysis was conducted.

RESULTS

We performed training and testing for classification of the following diseases: diabetes, heart disease, COPD, and stroke. For each disease respectively, we achieved an ROC AUC of 0.75, 0.70, 0.74, 0.69 on the test sets. ROC curves are displayed in Figure (1). For each of these results, a single radiologist with deep learning expertise manually inspected random samples of correct and incorrect predictions to ensure absence of any systematic errors. None was identified. Testing sets were confirmed to be an accurate representation of the training sets with regards to positive/negative example ratios.

CONCLUSION

Our 3D CNN model successfully predicted the likelihood of various diseases from lung cancer screening chest CT studies.

CLINICAL RELEVANCE/APPLICATION

The algorithm can be used to provide patients with useful health information about major diseases, in addition to the formal lung cancer screening interpretations by radiologists.

SSC03-02 Improving Specificity of Lung Cancer Screening CT Using Deep Learning

PURPOSE

Evaluate the utility of deep learning to improve the specificity and sensitivity of lung cancer screening with low-dose helical computed tomography (LDCT), relative to the Lung-RADS guidelines.

METHOD AND MATERIALS

We analyzed 42,943 CT studies from 14,863 patients, 620 of which developed biopsy-confirmed cancer. All cases were from the National Lung Screening Trial (NLST) study. We randomly split patients into a training (70%), tuning (15%) and test (15%) sets. A study was marked "true" if the patient was diagnosed with biopsy confirmed lung cancer in the same screening year as the study.A deep learning model was trained over 3D CT volumes (400x512x512) as input. We used the 95% specificity operating point based on the tuning set, and evaluated our approach on the test set. To estimate radiologist performance, we retrospectively applied Lung-RADS criteria to each study in the test set. Lung-RADS categories 1 to 2 constitute negative screening results, and categories 3 to 4 constitute positive results. Neither the model nor the Lung-RADS results took into account prior studies, but all screening years were utilized in evaluation.

RESULTS

The area under the receiver operator curve of the deep learning model was 94.2% (95% CI 91.0, 96.9). Compared to Lung-RADS on the test set, the trained model achieved a statistically significant absolute 9.2% (95% CI 8.4, 10.1) higher specificity and trended a 3.4% (95% CI -5.2, 12.6) higher sensitivity (not statistically significant).Radiologists qualitatively reviewed disagreements between the model and Lung-RADS. Preliminary analysis suggests that the model may be superior in distinguishing scarring from early malignancy.

CONCLUSION

A deep learning based model improved the specificity of lung cancer screening over Lung-RADS on the NLST dataset and could potentially help reduce unnecessary procedures. This research could supplement future versions of Lung-RADS; or support assisted read or second read workflows.

CLINICAL RELEVANCE/APPLICATION

While Lung-RADS criteria is recommended for lung cancer screening with LDCT, there is still an opportunity to reduce false-positive rates which lead to unnecessary invasive procedures.

PURPOSE

Lung-RADS is widely used to classify nodules detected on lung cancer screening CT. Using data from the National Lung Cancer Screening Trial (NLST), we examined whether integration of patient demographics, clinical history, and CT texture features could improve our ability to predict long-term lung cancer development. Since most screening CTs detect early stage lung cancers, we further examined if our algorithm could predict cancer progression and overall survival in patients with resected stage I lung cancers.

METHOD AND MATERIALS

Demographics, clinical history, and baseline CT images from 24,386 NLST participants were analyzed using survival machine learning (SML). Nodule volume was calculated by V=3.14LR2 where L=longest diameter, R=longest perpendicular diameter/2. Subjects were partitioned into 4 risk groups to test hazards ratios (HR). The SML partition was compared to that from Lung-RADS. For the stage I lung cancer subgroup, the time from lung cancer diagnosis to death was used as the SML endpoint.

RESULTS

At the time of baseline CTs, the 4 risk groups were classified by: high (largest nodule L>10mm, V>6358mm3; n=85), mid-high (largest nodule L>10mm, V<=6358mm3; n=1219), mid-low (largest nodule L=5~10mm, smoking>40 years; n=1736), and low (all

others; n=21346). Compared to our low risk group, HRs for time to lung cancer onset were 91.5, 11.1, 4.0 for high, mid-high, and mid-low risk groups respectively (all p<0.0001). In contrast, the HRs from Lung-RADS categories 4, 3, and 2 were 5.68, 1.27, and 0.75 respectively as compared to category 1 (p values: <0.0001, 0.056, 0.058). For stage 1 lung cancers, demographics, nodule margins, lymph node enlargement, and blood vessel involvement jointly affected the rate of cancer progression and overall patient survival.

CONCLUSION

Using the NLST data, our new classification outperforms Lung-RADS in stratifying risk and predicting long-term lung cancer development. Furthermore, in pathologically defined stage 1 patients who received surgery, our new classification can identify those with poor survival suggesting that it can do so independently of cancer stage.

CLINICAL RELEVANCE/APPLICATION

Our new classification outperforms Lung-RADS in stratifying risk and predicting long-term lung cancer development and can identify stage 1 patients with poor survival suggesting that it can do so independently of cancer stage.

SSC03-04 Effect of Semiautomated Segmentation and Computer-Aided Detection of Lung Nodules on Lung Cancer Screening with Low Dose CT: Experience from a Nationwide Lung Cancer Screening Project

Monday, Nov. 26 11:00AM - 11:10AM Room: E451A

PURPOSE

To evaluate the effect of semiautomated segmentation and computer-aided detection (CAD) system for lung nodule on lung cancer screening based on the Lung-RADS.

METHOD AND MATERIALS

We utilized the data from an ongoing nationwide multi-center lung cancer screening project with low dose chest CT. This project started with a visual assessment and manual measurement system (a manual system) and changed into a cloud-based software system which equipped with a semiautomated nodule segmentation and CAD system (a software system). In a software system, an average diameter of a nodule for the Lung-RADS was calculated on a plane showing the maximal cross sectional area of a nodule. For this study, an average diameter on axial planes was also calculated. We compared the number of detected lung nodules and distribution of Lung-RADS categories between two systems. When the results of before and after CAD were available (the number of cases, 2374), the effect of CAD was evaluated.

RESULTS

The number of cases and the number of nodules for both systems are as follows: a manual system, 1821 cases, 1630 nodules; a software system, 4665 cases, 6116 nodules. Significantly greater number of nodules (0.90 vs. 1.31 nodule/case) were detected at a software system. The size of nodule was significantly larger (5.5 vs. 4.6 mm) at a software system, but there was no significant difference in the size of nodules between two systems when axial planes were used in calculating an average diameter in a software system. Both the per-case (9.8% vs. 17.4%) and per-nodule (12.9% vs. 17.9%) proportion of positive test (category 3/4) were significantly higher at a software system. By applying the CAD results, not only the number of the detected nodules (0.77 vs. 1.23 nodule/case) but also the per-case proportion of positive test (11.6% vs. 17.1%) were significantly increased.

CONCLUSION

By applying a semi-automated segmentation and CAD system, the number of detected nodules and the proportion of positive test were significantly increased.

CLINICAL RELEVANCE/APPLICATION

Semiautomated segmentation and CAD have important effects on the Lung-RADS positive rate. Therefore, detailed guidelines should be provided for the use of software in lung cancer screening.

SSC03-05 Randomized Clinical Trial of CAD versus No CAD as First Reader of Lung Cancer Screening CT: Preliminary Report

PURPOSE

The accuracy of radiologists reading lung cancer screening CT in a previous study shows a false-negative rate (FN) of 3.5% to 8.1%. The purpose of this study was to assesses if CAD can reduce the FN and CT reading time.

METHOD AND MATERIALS

We conducted a randomized trial in 148 smokers participating in our ongoing Lung Cancer Screening Project (75M:73F, 66±7yrs, 59 ex- vs. 89 current-smoker). Chest CTs were randomized into two arms. In the CAD and Technician first arm (CAD+Tech-1st), CAD findings were displayed first, a technician accepted or rejected CAD findings and added probable nodule(s), then a chest radiologist accepted or rejected the CAD +Tech findings adding additional nodule(s). In the RAD-first arm (RAD-1st) the same radiologist read the CT first with CAD marks hidden, then turned on CAD to accept true nodules including those only found by CAD and delete the non-nodule CAD findings. The number of true nodules and reading time were recorded.

RESULTS

The reading times were 6.2 ± 3.4 min (range: 2-18) vs. 8.3 ± 5.4 min (range: 3-30) for CAD+Tech-1st vs. RAD-1st arms (p=0.012) for CTs with >=1 nodule; and 4.4±1.5 min (range: 2-10) vs. 8.7±9.5 min (range: 3-30) for those without nodules (p=0.07). By the three detection methods, 212 true nodules were found in 97 CTs in the CAD+Tech-1st arm. CAD detected 82 and technician added 93 true nodules, giving a combined sensitivity of 83%. There were 37/212 nodules found only by the radiologist; 12/37 were the most important nodule, and 1/37 was the only nodule that drove follow-up. In the RAD-1st arm 71 true nodules were found in 51 CTs; 36/71 (51%) were found by both CAD and radiologist. The radiologist missed 2 true nodules in 2 participants (2/51, 4%) which were detected by CAD and altered their follow-up protocol. The radiologist's detection sensitivity slightly increased with CAD (97% to 100%). CAD missed 33/71(46%) true nodules found by the radiologist, 16/33 (48%) were key nodules and 11/16 were the only nodule, changing follow-up.

CONCLUSION

CAD+Tech speed up the radiologist's nodule detection on screening chest CT. CAD detected nodules in 4% subjects where no nodule was identified by the radiologist, changing imaging follow-up protocol.

CLINICAL RELEVANCE/APPLICATION

While CAD+Tech as first reader cannot replace the radiologist, CAD could play an important role in lung cancer screening by saving radiologists' time, and importantly reduce their FN rate by 4%.

SSC03-06 Understanding Gaps Between Mental Health and Radiology Care: Population-based Cross-Sectional Survey Analysis of Lung Cancer Screening Eligibility and Smoking Prevalence Among Patients with Mental Illness

PURPOSE

Prior studies have found that patients with mental illness are more likely to smoke compared with patients without mental illness. Lung Cancer Screening (LCS) with LDCT decreases lung cancer mortality in eligible current or former smokers. There is limited population-based information about LCS eligibility in patients with mental illness. Our purpose was to determine if patients with self-reported mental illness are more likely to be eligible for LCS and smoking cessation interventions compared to patients without mental illness using nationally representative federal cross-sectional survey data.

METHOD AND MATERIALS

Retrospective analysis of 2015 National Health Interview Survey (NHIS), a nationally representative, federal cross sectional survey was conducted. Individuals 55-77 yrs without lung cancer were included. The proportion of survey participants eligible for LCS was calculated and compared in patients with and without self-reported mental illness. Multiple variable logistic regression analyses were conducted comparing LCS eligibility in patients with and without self-reported mental illness, adjusted for potential confounders (age, race, and insurance status). Adjusted odds ratios were calculated with 95% confidence intervals. Analyses were performed accounting for complex survey design elements.

RESULTS

11,325 individuals between ages 55-77 were included (mean age 64.1, 52.8% female, 74.9% white) of whom 2.8% reported at least

one mental illness. Of individuals with self reported mental illness, 18.7% met eligibility criteria for LCS and 25.8% were current smokers. Of individuals without self reported mental illness, 10.6% met eligibility criteria for LCS and 12.9% were current smokers. Patients self-reporting mental illness were more likely to be eligible for LCS (Adjusted OR 1.89, 95% CI 1.30 to 2.75, p = 0.001) and more likely to be current smokers (Adjusted OR 2.20, 95% CI 1.59 to 3.07, p < 0.001) than patients without mental illness.

CONCLUSION

Patients with self-reported mental illness have a higher smoking prevalence and are nearly twice as likely to be eligible for LCS compared with patients without mental illness.

CLINICAL RELEVANCE/APPLICATION

Radiologists have an opportunity to collaborate with psychiatry and primary care in developing targeted LCS outreach efforts for patients with mental illness who are at increased risk of developing lung cancer due to their higher smoking prevalence.

SSC03-07 Lung Cancer Screening in a Socioeconomically Disadvantaged Population: Baseline and 1st Annual Rescreening Results

PURPOSE

To describe the results of the first two rounds of screening of our clinical low-dose CT lung cancer screening program targeting a minority, socioeconomically disadvantaged, high-risk population different from that studied in the National Lung Screening Trial.

METHOD AND MATERIALS

All participants met USPSTF and/or NCCN eligibility criteria for lung cancer screening. A coordinator enrolled eligible individuals, scheduled their screening exams, and organized their transportation.

RESULTS

1029 individuals were referred from 7/21/2015 through 3/20/2018. 119 individuals declined screening, and 230 were unable to be contacted. Of 717 participants who agreed to participate, 411 met eligibility criteria for lung cancer screening. 370 patients underwent their baseline LDCT during this time period. 203 males (55%) and 167 females received baseline LDCT, with a mean age of 60 years. The median pack-years was 42 (range 20-132), and 81% of participants were current smokers. The ethnic makeup of the population was 77% black, 9% white, 8% Hispanic/Latino, and 5% Asian. 57% of participants had no more than a high school education. 33% of participants reported occupational exposure to one or more lung carcinogens. 84% (312) of patients received a Lung-RADS score of 1 (92) or 2 (220), 8% (29) received a score of 3, 5% (19) a score of 4A, and 3% a score of 4B (8) or 4X (2). 3 patients have been diagnosed with lung cancer to date: 1 stage IIB, 1 stage IIIB, and 1 stage IV. 28% (105) of patients had potentially significant incidental findings including interstitial lung disease (16), severe emphysema (14), aortic aneurysm (7), moderate-severe coronary calcifications (45), extrapulmonary masses (32), and pulmonary hypertension (4). 54% (147/271) of participants who were due for annual rescreening returned for their first annual LDCT. 93% (136) of these patients received a Lung-RADS score of 1 (21) or 2 (115), 3% (4) received a score of 3, 1% (2) a score of 4A, and 3% a score of 4B (5) or 4X (0).

CONCLUSION

Lung cancer screening with LDCT in a minority, socioeconomically disadvantaged, high-risk population is feasible but may yield a different lung cancer profile than screening in more privileged communities. Adherence to annual rescreening and follow-up recommendations is challenging in this population.

CLINICAL RELEVANCE/APPLICATION

Minority, socioeconomically disadvantaged populations may experience different benefits from LDCT lung cancer screening.

kessler.abraham@gmail.com

PURPOSE

To compare the performance of the Vancouver Risk Calculator (VRC) with ACR Lung-RADS for a lung cancer screening cohort in an urban, diverse clinical setting.

METHOD AND MATERIALS

IRB approval was obtained. All lung cancer screening patients who had their initial screening CT from December 2012-June 2016 demonstrating a nodule comprised the study population. Each exam was assigned a Lung-RADS score, with 4A and 4B considered positive. The VRC calculates the risk of cancer at different thresholds using 9 patient and imaging variables, with a 5% threshold considered positive. Analysis was performed on a per-patient level based on the largest nodule. Follow-up information was obtained via EMR, cancer registry and NDI. Patients with initial studies suspicious for malignancy but without histologic confirmation were adjudicated on a case-by-case basis. Performance characteristics to predict lung cancer were compared for Lung-RADS and VRC.

RESULTS

486 patients, 261(53.7%) women, mean age 63±5.2, comprised the study population. Mean follow-up time was 36.9± 11.1 months, and 61(12.6%) patients were lost to follow-up. Lung cancer was diagnosed in 35(7.2%). Lung-RADS had 10 FP and 14 FN while VRC 5% had 30 FP and 8 FN. Overall sensitivity, specificity and accuracy for Lung-RADS was 61.1%, 97.8%, and 94.9% and for VRC 5% was 77.8%, 93.3%, and 92.2%, respectively.

CONCLUSION

In comparison with Lung-RADS, the VRC demonstrated higher sensitivity but lower specificity and accuracy in predicting malignancy among patients in a diverse clinical lung cancer screening program.

CLINICAL RELEVANCE/APPLICATION

LungRADS and VRC achieved complementary results in a diverse urban clinical lung cancer screening program. Use of the two, in concert, may improve lung cancer prediction.

SSC03-09 Lung MRI as a Cost-Effective Alternative to Low-Dose CT Lung Cancer Screening: A Markov Cohort Analysis

bdallen@northwestern.edu

PURPOSE

The purpose of this study was to evaluate the potential performance of lung MRI (MRI) vs. low dose CT (LDCT) using a Markov model of lung cancer screening. We hypothesized that MRI would be a cost-effective alternative to LDCT.

METHOD AND MATERIALS

We converted the MISCAN Lung microsimulation of lung cancer progression into a Markov cohort model with transition probabilities based on histology/stage. Our model uses published data to specify lung cancer incidence and background non-lung cancer mortality based on gender, age and smoking burden, and survival after diagnosis by gender, histology and stage. Published LDCT screening sensitivity (Sn) and specificity (Sp) by stage/histology was used to populate the LDCT model parameters. For MRI, the Sn and Sp were based on published data of solid nodules using size and T2 contrast-to-noise ratio. Our model follows a large cohort of age-60 males with 2 packs/day smoking history for 20 years. The time-0 composition of the cohort was a mixture of well and undiagnosed cancer patients from the model when run from age 42. At each annual screening, portions of the surviving cohort experience true/false, positive/negative outcomes with true positives moving to treatment. Costs for screening LDCT ($256), work-

up, and treatment were extracted from CMS procedure cost data and the literature. Sensitivity analysis was performed on Sn/Sp of MRI and costs of MRI. Results of interest include life-years/patient (LYs), net monetary benefit (NMB), and cost-effectiveness (C/E) of MRI relative to LDCT.

RESULTS

LYs for MRI screening were 13.28 vs. 13.29 for LDCT. Using an acceptable cost/LY of $100,000, MRI resulted in a net-monetary benefit (NMB) of $3,744 over LDCT. MRI saves $2656/patient over LDCT, while losing only 3.97 life days, for a favorable C/E ratio of $244,189/LY. Cost ranging from $256 to $375 result in a favorable C/E ratio for MRI.

CONCLUSION

Based on this simulation, MRI provides an equivalent LY benefit with cost-savings over LDCT lung cancer screening at reasonable MRI costs. This finding is driven by improved specificity of MRI for solid nodule characterization.

CLINICAL RELEVANCE/APPLICATION

Markov simulation of a high-risk screening cohort shows that Lung MRI has the potential to be a cost-effective alternative to low-dose CT screening.

A.devito@campus.unimib.it

PURPOSE

To evaluate dose reduction and image quality of 80 kV CT pulmonary angiography (CTPA) reconstructed with model-based iterative reconstruction (IMR), and compared with 100 kV CTPA with hybrid iterative reconstruction (iDose4).

METHOD AND MATERIALS

One hundred and fifty-one patients were prospectively investigated for pulmonary embolism; a study group of 76 patients underwent low-kV setting (80kV,automated mAs) CTPA study, while a control group of 75 patients underwent standard CTPA protocol (100kV; automated mAs); all patients were examined on 256 MDCT scanner (Philips iCTelite). Study Group images were reconstructed using IMR while the Control Group ones with iDose4. CTDIvol, DLP and ED were evaluated. Region of interests placed in the main pulmonary vessels evaluated vascular enhancement (HU); signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) were calculated.

RESULTS

Compared to iDose4-CTPA, low kV IMR-CTPA presented lower CTDIvol (6.41 ± 0.84 vs 9.68 ± 3.5 mGy) and DLP (248.24 ± 3.2 vs 352.4 ± 3.59 mGy x cm), with ED of 3.48 ± 1.2 vs 4.93 ± 1.8 mSv. Moreover IMR-CTPA showed higher attenuation values (670.91 ± 9.09 HU vs 292.61 ± 15.5 HU) and a significantly higher SNR (p<0,0001) and CNR (p<0,0001). The subjective image quality of low kV IMR-CTPA was also higher compared with iDose4-CTPA (p<0,0001).

CONCLUSION

Low dose CT with IMR represents a feasible protocol for the diagnosis of pulmonary embolism in the emergency setting and permits to achieve excellent diagnostic images (in terms of subjective quality) with extremely low noise, and a significant reduction of the dose led to the patient (in terms of mSv) within reasonable reconstruction times (less than 120 seconds).

CLINICAL RELEVANCE/APPLICATION

Low kV IMR approach allows a significant dose reduction of CTPA studies improving attenuation values, SNR and CNR in the pulmonary vessels, as compared with standard kV iDose4-CTPA.

SSC04-02 A Proposal of a New System Score to Evaluate With Lung Ultrasound the Necessity of a Drainage Tube in Pneumothorax in Emergency Room

Monday, Nov. 26 10:40AM - 10:50AM Room: S504AB

Participants
Maria Luisa De Cicco, MD, Roma, Italy (*Presenter*) Nothing to Disclose
Vittorio Miele, MD, Florence, Italy (*Abstract Co-Author*) Nothing to Disclose

stefianni66@gmail.com

PURPOSE

Aim of this study was to evaluate the validity of a new system score and its utility in the Emergency Room to estabilish the necessity to drainage pneumothorax diagnosed by ultrasound in unstable adults major trauma.

METHOD AND MATERIALS

Retrospective observational study that involved, from January 2015 to January 2018, 274 adults patients with pneumothorax, evaluated by lung ultrasound in Emergency Room during Primary Survey. All ultrasound were performed with portable ultrasound machine in Emergency Room, with patients lying on the spinal board stretcher. It was applied a system score which included the evaluation of the lung point site (parasternal =1, emiclavear =2 or axillary line=3), the presence of pleural effusion (><300 ml=1 o 0) and the position of the heart (with o without dislocation=1 o 0). Cut off estabilished to indicate the necessity of the thorax drainage was 4. All patients underwent to MDCT (gold standard) and the results compared.

RESULTS

Among the enrolled patients with pneumothorax 184/274 had a score > 4 and the necessity of a drainage was indicated on the report. Of these in 164 the necessity was confirmed by CT, while in 20 the patients were just observed. Among the 20 'false positive to need drainage' of our retrospective review, someone had a high BMI (8), someone had subcutaneous emphysema (5), while in the other or there was an overvaluation by the US evaluation or the patients conditions improved (7).

CONCLUSION

Our data regarding the validity of a new system score should be useful in deciding the necessity of a draining tube in major trauma unstable patients. This score would allow an early diagnosis and a promptly therapeutic decision, avoiding wasting time, essential in patients with many traumatic lesions and above all with serious pneumothorax.

CLINICAL RELEVANCE/APPLICATION

Identify an useful new scoring system, helpful to estabilish the necessity to drainage pneumothorax diagnosed by ultrasound, in unstable adults major trauma

SSC04-03 Identifying Patients with Low Cardiac Output Using Vessel Density at CTPA

PURPOSE

Cardiac output (CO) is an important metric that has diagnostic and prognostic value in emergency and inpatient settings. However, determining CO currently requires invasive or costly procedures such as Swan-Ganz catheterization (SGC) or cardiac MR (CMR). CT for pulmonary angiography (CTPA) is a commonly performed examination that provides a snapshot of exogenously administered contrast as it distributes through the thoracic vasculature in a manner chiefly determined by CO. We hypothesized that by measuring attenuation in different vessels we could (1) identify patients with reduced CO and, potentially, (2) quantify CO.

METHOD AND MATERIALS

We retrospectively identified patients who underwent SGC or CMR within 14 days of CTPA between 1/1/2006 to 12/30/2016. Using CO values from SGC or CMR as the gold standard, patients were stratified into three groups: CO < 4 L/min (low), 4-8 L/min (normal), and over 8 L/min (high). All CT studies were performed using a standardized protocol with a fixed delay of 22 sec and an injection rate of 4 cc/s. For each patient, density (HU) was measured in the superior vena cava [SVC], main pulmonary trunk [PT], and ascending aorta [AO] on a single mid-thoracic transaxial slice. Densities and density differences were then compared with measured vales of CO.

RESULTS

We identified 119 patients with concurrent CO measurements and CTPA studies within the study period. Compared to patients with normal CO (n=76, 63.9%), patients with low CO (n=35, 29.4%) exhibited higher attenuation in the SVC (1305±846 vs 944.4±556.8 HU, p=0.026) and PT (518.4±149.6 vs 385.3±122.4 HU, p<0.001). Adjusting for body surface area, PT-AO difference predicts low CO (OR per unit increase 1.007, 95% CI 1.004-1.010, p<0.001). ROC analysis yielded a PT-AO difference threshold of 130 HU for differentiating low from normal CO, with sensitivity and specificity of 74.3% and 87.7% (AUC 0.776, p<0.001).

CONCLUSION

This study provides a simple approach to estimate low CO status by measuring vessel density on a single transaxial CTPA image at the level of the mid-ascending aorta. We found that the greater the attenuation difference between the PT and AO, the greater the odds of low CO, with a difference of 130 HU serving as a useful threshold distinguishing low from normal CO.

CLINICAL RELEVANCE/APPLICATION

Using a standardized CTPA protocol it may be possible to confidently identify patients with reduced cardiac output.

SSC04-04 Multi Factorial Comparative Study of Dual Source CT Scanners in Acute Pulmonary Embolism

Monday, Nov. 26 11:00AM - 11:10AM Room: S504AB

Participants
Waleed Abdellatif, MD, Vancouver, BC (*Presenter*) Nothing to Disclose
Savvas Nicolaou, MD, Vancouver, BC (*Abstract Co-Author*) Institutional research agreement, Siemens AG
Heiko Schmiedeskamp, PhD, Malvern, PA (*Abstract Co-Author*) Employee, Siemens AG
Jennifer Powell, Vancouver, BC (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

waleed.abdellatif@vch.ca

PURPOSE

To compare mean acquisition time, image quality and diagnostic accuracy of two dual-energy CT scanners for the evaluation of acute pulmonary embolism (PE).

METHOD AND MATERIALS

Total of 50 scans on the 2nd generation dual source SOMATOM Definition Flash CT scanner (the Flash) and 49 scans on the 3rd generation dual source SOMATOM Force (the Force) were included. Scans with inadequate opacification of pulmonary artery or known chronic PE were excluded. Imaging acquisition parameters were adjusted to be the same on both the Force and the Flash. In a randomized blinded design, two radiologists independently reviewed both sets of scans in two settings (3-week interval) for image quality using a 5-point scale. The interobserver reliability and diagnostic accuracy were calculated for each reviewer. Diagnosis of acute PE was made using clinical data (acute chest pain), laboratory data (D-Dimer > 500 ug/L) and CTPA.

RESULTS

Mean acquisition time for the Force (x= 2.81 sec, SD= 0.1) and the Flash (x= 9.7 sec, SD = 0.15) was found to be very statistically significant (P= 0.0001; 95% CI = 6.8 - 6.9) with the Force 3.4 times faster than the Flash. The mean image quality was found to be 4.47/5 and 4/5 for the Force and the Flash respectively with statistical significance (P= 0.0064 on the unpaired t-test; 95% CI= 0.80-0.13). Interobserver reliability for image quality indicates strong agreement on both, the Force (K= 0.83, p <0.005) and the Flash-generated scans (k= 0.85, p < 0.005).Acute PE was diagnosed in 17 cases on the Force and in 21 cases on the Flash. Diagnostic accuracy was 94.1% and 98.2% on the Force and 90.2% and 94.8% on the Flash for reviewers one and two respectively. Although diagnostic accuracy was higher on the Force, the difference wasn't statistically significant. Study limitations includes retrospective design and Berkson's selection bias as the Force was routinely used for emergency patients while the Flash was used for inpatients.

CONCLUSION

Image quality is significantly higher on the Force CT scanner with significantly lower mean acquisition time and less motion artifact in comparison to the Flash.

CLINICAL RELEVANCE/APPLICATION

The improved image quality and speed of the Force CT scanner with resultant less motion artifact and repeated studies could be particularly useful in emergency radiology setting with large patient volume.

SSC04-05 Axial or Helical? CT Imaging of the Chest for Uncooperative Emergency Patients with 16-cm Wide Detector CT

Monday, Nov. 26 11:10AM - 11:20AM Room: S504AB

liyanan976@163.com

PURPOSE

To compare image quality and radiation dose between the fast-helical mode (FHM) and two-axial mode (TAM) in chest CT imaging for uncooperative emergency patients with 16-cm wide detector CT scanner.

METHOD AND MATERIALS

Thirty emergency patients who were unconscious or uncooperative with the breathing instructions underwent chest CT were prospectively divided randomly into two groups: FHM Group (n=15, helical scan mode with 80mm detector coverage and pitch 0.992:1), TAM Group (n=15, axial scan mode with 160mm detector coverage, two scans). Both groups used the 0.28s rotation speed and automatic tube current modulation. All scans were performed in free-breathing. CT value, image noise and signal-to-noise ratio (SNR) were measured at each of the following locations: descending thoracic aorta, lung parenchyma and paraspinal muscle at the level of the carina. Two radiologists assessed the images for subjective image quality, motion artefacts and diagnostic confidence. The volume CT dose index (CTDIvol) and dose-length product (DLP) were evaluated from the dose reports, and effective dose was calculated. All measurements between the two groups were statistically compared.

RESULTS

The mean total exposure time was significantly shorter for TAM group than FHM group (0.56s vs.1.12s, P<0.001). Image quality was generally better with TAM than with FHM (diagnostic confidence score, 3.87 vs. 3.47, P<0.05); However, there was no

significant difference in CT value, image noise and SNR between two groups. The DLP value was higher in FHM than TAM (123.92±38.54mGy·cm vs. 94.22±33.63mGy·cm, P=0.041), while CTDIvol was not significantly different. TAM group reduced the total effective radiation dose by 24% compared to FHM (1.32±0.50 mSv vs. 1.73±0.54mSv).

CONCLUSION

The use of the two-axial mode further reduces the scan time in chest CT for emergency patients and ensures good image quality with 24% radiation dose reduction, compared with chest CT that uses the fast-helical scan with 80mm collimation.

CLINICAL RELEVANCE/APPLICATION

The two-axial scan mode can be used for lung evaluation in uncooperative emergency patients in free breathing to obtain satisfactory image quality while reducing radiation dose.

SSC04-06 Utility of 3D Post-Processing Cinematic Rendering Reconstruction Images in Acute Trauma Setting: Initial Observations

Monday, Nov. 26 11:20AM - 11:30AM Room: S504AB

Participants
Sadia R. Qamar, MBBS, Vancouver, BC (*Presenter*) University of British Columbia Hasamaster Research Agreement with Siemens Medical Health Care
Savvas Nicolaou, MD, Vancouver, BC (*Abstract Co-Author*) Institutional research agreement, Siemens AG

Vahid Mehrnoush, Vancouver, BC (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

raashidsadia@gmail.com

PURPOSE

Multiple post-processing reconstruction techniques based on volumetric CT datasets are used to generate three-dimensional (3D) images to better depict complex anatomical details. Volume rendering (VR) is frequently used as a standard 3D technique, however recently an FDA-approved alternative called Cinematic Rendering (CR) is emerging with vast clinical potentials (1,2). Contrary to traditional VR reconstruction, CR utilizes a global illumination model to create high definition photo-realistic images. We describe our initial experience with CR images in the setting of acute trauma.

METHOD AND MATERIALS

A set of polytrauma patients with ISS score >16 with simple to complex injuries presenting to Vancouver General Hospital, level 1 trauma center were evaluated. Source DICOM images using a 2nd generation 128-slice dual-source CT (Somatom Definition Flash, Siemens Healthineers, Forchheim, Germany) were used to create CR images. Cinematic Rendering software (Siemens Syngo.via Frontier) was used applying default and customized presets. CR images were assessed for image quality, depth and shape perception, delineation of osseous, vascular, soft tissue and solid organ anatomy in comparison to VR images. The images were also evaluated for their role in clinical decision making and education. Multiple trauma surgeons assessed the images using Likert scale analysis with 1 being much lower, 3 equivocal, and 5 much higher. Frequencies, percentages, mean and standard deviation were calculated.

RESULTS

CR images were rated higher than VR images with a mean+/- SD of 4.0+/-0.8. 67 % of trauma surgeons categorized CR images as much higher for use as an education tool and 61% graded them as higher in helping with clinical decision compared to VR images.

CONCLUSION

Our observations are one of the very few initial studies to evaluate the clinical utility of CR images. Understanding complex and challenging anatomical and pathological details are imperative for better patient management from a trauma surgeon assessment. CR provides remarkable details relative to VR reconstructions in context of complex acute trauma

CLINICAL RELEVANCE/APPLICATION

Cinematic Rendering is a promising novel technique to display visually receptive 3D photorealistic high definition images with exquisite anatomical details. Formal evaluations and research is needed to assess the CR images in order to understand their clinical application in patient management.

SSC04-07 Improving Pulmonary Embolism Detectability for Computer-Aided Detection Software Using Optimal Kev Monochromatic Images in Dual-Energy Spectral CT

Monday, Nov. 26 11:30AM - 11:40AM Room: S504AB

Participants

Chenwang Jin, Xi'an, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To compare pulmonary embolism detectability using computer-aided detection (CAD) software with optimal keV monochromatic images and conventional images.

METHOD AND MATERIALS

Retrospectively analyzed CT images of 20 patients with clinically proven pulmonary embolism (PE). These patients underwent CT pulmonary angiography (CTPA) with spectral imaging mode. The conventional images (140kVp polychromatic, group A) were reconstructed. Using the standard Gemstone Spectral Imaging (GSI) viewer on an advanced workstation (AW4.6), an optimal energy level (group B) could be automatically obtained. The images in two group were independently analyzed for detecting PE using a commercially available CAD software. Two experienced radiologists reviewed all images and recorded the number of emboli, and the results were used as the gold standard. The attenuation in the main pulmonary artery (MPA) and the embolus (in the most substantial part of the embolus) were measured. The difference in attenuation (MPA-embolus), as well as the detectability for pulmonary embolism in each case (sensitivity, false positive rate) were calculated. Data were statistically compared between the two groups.

RESULTS

The optimal energy levels were 62.4keV. The attenuation in the MPA, difference in attenuation (MPA-embolus) for group A and B were (314.46±81.41HU vs. 446.30±151.88HU) and (281.89±73.82HU vs. 404.75±138.74HU), respectively (all $p<0.001$). The mean sensitivity for pulmonary embolism detection in group A was 74.63±6.16%, which was lower than the 82.17±4.51% in group B ($t=-4.26$, $p<0.001$). The mean false positive rate in group A was 32.71±4.89%, which was higher than the 13.41±3.02% in group B ($t=13.41$, $p=0.00$).

CONCLUSION

Compared with conventional images, the combination of optimal keV monochromatic images and CAD improves the diagnostic accuracy of CAD.

CLINICAL RELEVANCE/APPLICATION

The combination of optimal keV monochromatic images and CAD could improve the detection rate for emboli.

SSC04-08 Implementation of Fully Automated Computer-Aided Detection of Nodules in The Lung Bases on Emergent Abdominal CT Scans: Accuracy and Effect on Workflow

Monday, Nov. 26 11:40AM - 11:50AM Room: S504AB

Participants
Amirhossein Mozafarykhamseh, MD, Chicago, IL (*Presenter*) Grant, Siemens AG
Tugce Agirlar Trabzonlu, MD, Chicago, IL (*Abstract Co-Author*) Grant, Siemens AG
Pamela J. Lombardi, MD, Chicago, IL (*Abstract Co-Author*) Nothing to Disclose
Rishi Agrawal, MD, Chicago, IL (*Abstract Co-Author*) Speakers Bureau, Boehringer Ingelheim GmbH
Vahid Yaghmai, MD, Chicago, IL (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To assess the value of fully automated computer-aided diagnosis (CAD) for detection of lung nodules on emergent abdominal CT studies in.

METHOD AND MATERIALS

Abdominal CT scans of 50 patients in the emergency department were reviewed. A radiologist with 5 years' experience (RAD) reviewed the scans to detect pulmonary nodules in the lung bases. In order to simulate the emergency setting, time limit of 30 seconds was set in each case for RAD to review image datasets. The CAD detection performance was also evaluated in the same session by RAD. CAD nodule detection was fully automated and required no additional processing time by RAD. Fisher`s exact test and T-test were used to determine the differences between the rate of detection between RAD and CAD.

RESULTS

A total number of 54 nodules were detected by RAD in 50 patients (28 male, mean±SD age, 51.2±17.6 years). Adding the CAD increased the rate of detection by 30% (1.47 vs. 1.13 nodule/scan, $P<0.05$). Moreover, there was no significant difference in the rate of missed nodules per scan between CAD and RAD (0.33 nodule /scan vs. 0.25 nodule/scan), respectively. 25 out of 74 nodules detected by CAD were false positives .

CONCLUSION

Using fully automated CAD may significantly improve the performance of the radiologist in detecting nodules located in the lung bases on abdominal CT scans obtained in the emergency department.

CLINICAL RELEVANCE/APPLICATION

The role of CAD as a second reader may improve detection of lung base nodules on emergency department abdominal CT scans.

SSC04-09 Spectrum of Radiological Manifestations of Melioidosis, Association with Risk Factors, and Its Role in Prognostication of Clinical Outcome

Monday, Nov. 26 11:50AM - 12:00PM Room: S504AB

Participants
Leena Robinson Vimala, MD, Vellore, India (*Presenter*) Nothing to Disclose

PURPOSE

Melioidosis being a mimicker of its more common clinical counterpart tuberculosis, is often mismanaged.The primary objective is to describe the spectrum of radiological manifestations of melioidosis. Secondary objectives are to evaluate the association between the organ involvement, known risk factors, predisposing conditions and also to predict effect on clinical outcome.

METHOD AND MATERIALS

Retrospective image analysis of all culture proven cases of Burkholderia pseudomallei,between January 2011 & October 2017 was done. Demographic data, clinical characteristics, risk factors and clinical outcome were anlaysed. Unfavourable clinical outcome considered were those patients with severe disease condition requiring ICU admission for administration of ionotropes, requirement of ventilation or death.

RESULTS

194 patients (162 males) with median age of 45 years,were included.Among the risk factors, diabetes mellitus was most common (63%), followed by alcohol abuse (28%).Table 1 demonstrates the radiological manifestation of organ/ system involvement of melioidosis.Patients with diabetes were found to have increased incidence of liver, spleen, bone and soft tissue involvement ($p<0.05$).Significant association of diabetes with liver, spleen and bone and soft tissue involvement seen, having odds ratios 3.213 (95% CI:1.048 - 9.855;p=0.04),3.478 (95% CI:1.728-7;p=<0.001)&2.668 (95% CI:1.232 - 5.778;p=<0.001) respectively. Statistical significant difference was identified in the melioidosis involvement of genitourinary tract between the positive and negative TB group. 25% of patients suffered unfavourable outcome. Mortality was 11%. Using univariate binary logistic regression analysis,lung involvement was found to have 4.3 times risk for unfavourable outcome (95% CI 1.971 - 9.496; $p< 0.001$),whereas spleen and lymph node involvement, protected from unfavourable outcome (odds ratio being 0.202 & 0.457 respectively).

CONCLUSION

The constellation of imaging findings could mimic disseminated tuberculosis or other pyogenic infection. Combination of organ involvement, associated superficial soft tissue involvement are imaging diagnostic clues.Knowledge about the radiological manifestations of melioidosis is essential for accurate diagnosis and management.

CLINICAL RELEVANCE/APPLICATION

Present study is the largest study that has illustrated the radiological manifestations of melioidosis and its association with clinical outcome and risk factors.

PURPOSE

To evaluate the clinical performance of the ACR Ultrasound Liver Reporting and Data System (US LI-RADS) Version 2017 for detecting hepatocellular carcinoma (HCC) in a population of patients at high risk for HCC.

METHOD AND MATERIALS

In this retrospective, multicenter, HIPAA-compliant, IRB-approved study, patients at 5 sites had undergone screening liver ultrasound from Jan-Sep 2017 and US LI-RADS visualization scores and management categories were assigned on a clinical basis. Ultrasound reports and patient records were then retrospectively reviewed and any follow-up imaging studies and/or pathologic reports recorded. Descriptive statistics were performed.

RESULTS

2050 patients at high risk for HCC (1078 men and 972 women; mean age 57.7 years) were included. The most common indications were cirrhosis (n=1054; 51.3%), non-cirrhotic HBV (n=555; 27.1%), and non-cirrhotic HCV (n=234; 11.4%). Among patients with cirrhosis, the most common etiologies were HCV (n=396; 19.4%), alcohol (n=194; 9.5%), and HBV (n=187; 9.2%). US LI-RADS scores had been assigned by 69 different readers with mean 19.3 years experience post-residency. US LI-RADS categories were: US-1 (Negative) in 90.4% (n=1854): US-2 (Subthreshold) in 4.6% (n=95); and US-3 (Positive) in 4.9% (n=101). Visualization scores were: A (No or minimal limitations) in 76.8% (n=1575); B (Moderate limitations) in 18.9% (n=388); and C (Severe limitations) in 4.2% (n=87). Confirmatory tests including contrast enhanced CT/MR (n=212) or histopathology (n=9) were available for 221 patients. Treating US-2 and US-3 as positive test results and LR-3, LR-4, LR-5, or LR-M imaging observations at CT/MR or tissue diagnosis of HCC as positive clinical outcomes, the sensitivity of US LI-RADS was 77.5%, specificity 58.9%, PPV 40.2%, and NPV 88.1%.

CONCLUSION

US LI-RADS visualization scores in over 2000 patients demonstrated >95% of US screening exams were diagnostically acceptable. Approximately 90% of exams were interpreted as negative, 5% subthreshold, and 5% positive. In the subset of patients with confirmatory testing, US LI-RADS exhibited moderately high sensitivity (77.5%) and NPV (88.1%), key characteristics of a screening test.

CLINICAL RELEVANCE/APPLICATION

During the first year after its release, ACR US LI-RADS was adopted into clinical practice and demonstrated promising clinical performance for HCC screening in multiple academic medical centers.

PURPOSE

This study aimed to evaluate the performance of the Liver Imaging Reporting and Data System (LI-RADS) v2017 in differentiating hepatocellular carcinoma (HCC) from intrahepatic cholangiocarcinoma (IHCC) and combined hepatocellular-cholangiocarcinoma (cHCC-CC) on gadoxetic acid-enhanced magnetic resonance imaging (MRI), and to determine its postsurgical prognostic implications.

METHOD AND MATERIALS

Our institutional review board approved this study and waived the requirement for informed consent. A total of 194 patients with single primary liver cancers surgically resected (53 cHCC-CCs, 44 IHCCs, and 97 HCCs) from cirrhotic livers were evaluated on gadoxetic acid-enhanced MRI. Two independent readers analyzed each nodule and assigned a LI-RADS category. Overall survival (OS), recurrence-free survival (RFS), and their associated factors were evaluated using the Kaplan-Meier method, the log-rank test, and the Cox proportional hazard model.

RESULTS

The sensitivity and specificity of the LR-5 category for diagnosis of HCC were 76.3% (74/97) and 84.5% (82/97), respectively; most (86.7%) false-positive diagnoses were misclassification of cHCC-CCs. In the multivariate analysis, the LI-RADS category was a significant independent factor for OS (HR=3.88; p<0.001) and RFS (HR=2.26; p=0.010). The LR-M category was associated with poorer OS and RFS than the LR-4 or LR-5 categories for all primary liver cancers (p<0.001, both), HCCs (p=0.012 and p=0.009, respectively), and cHCC-CCs (p<0.001 and p=0.002, respectively). The OS and RFS of the cHCC-CCs categorized as LR-4 or LR-5 did not significantly differ from those of HCCs (p=0.535 and p=0.074, respectively).

CONCLUSION

LI-RADS correctly classifies most HCCs and IHCCs, whereas differentiation of cHCC-CC from HCC presents a challenge. The LI-RADS category may predict the postsurgical prognosis of primary liver cancers, independent of the pathologic diagnosis.

CLINICAL RELEVANCE/APPLICATION

The LI-RADS v2017 guidelines correctly classify most HCCs and IHCCs, whereas differentiation of cHCC-CC from HCC is challenging, reducing the specificity of LI-RADS in the diagnosis of HCC. The LI-RADS category allows prediction of the postsurgical prognosis of primary liver cancers, independent of the pathologic diagnosis of the tumor.

SSC05-04 Liver Imaging Reporting and Data System: Frequency of Category Adjustment Using Ancillary Features on CT and MRI in Clinical Practice

vichka17@hotmail.com

PURPOSE

The Liver Imaging Reporting and Data System (LI-RADS, LR) uses ancillary features (AFs) to adjust the category code assigned by major features (MFs). This study assessed the frequency with which AFs are used to adjust category on CT and MRI in clinical practice.

METHOD AND MATERIALS

All MR and CT reports issued with a standardized LI-RADS template at one tertiary care center between 3/16-3/18 were identified. For each reported LR-3, LR-4, and LR-5 observation, the presence of every MF and every AF was extracted retrospectively from the clinical report. LI-RADS categories then were assigned using the v2017 LI-RADS algorithm based on the reported MFs and AFs and following the v2017 instructions: increase category by one and up to LR-4 for >=1 AF favoring malignancy (AF-M), decrease by one with >=1 AF favoring benignity (AF-B), and no change with >=1 AF-M and >=1 AF-B. Results were summarized descriptively.

RESULTS

314 patients (209 [66%] male, mean age 65 [±10] years) were identified. They had a total of 548 observations (median size 13mm, IQR 9-20mm) including 441 (median size 13mm, IQR 9-20mm) reported on MRI and 107 (median size 15mm, IQR 10-22mm) reported on CT. Without applying AFs, 42% (232/548) of all observations were categorized LR-3, 29% (161/548) LR-4, and 28% (155/548) LR-5; 45% (198/441) of MRI observations were categorized LR-3, 28% (124/441) LR-4, and 27% (119/441) LR-5; 32% (34/107) of CT observations were categorized LR-3, 34% (37/107) LR-4, and 34% (36/107) LR-5. Application of AFs caused the LI-RADS category to be increased in 24% (127/524) and decreased in 4% (24/524) of all observations, increased in 28% (123/441) and decreased in 5% (22/441) of MR observation, and increased in 4% (4/107) and decreased in 2% (2/107) of CT observations. In particular, AFs caused 55% (127/232) of LR-3 observations overall, 62% (123/198) of LR-3 MRI observations, and 12% (4/34) of LR-3 CT observations to be upgraded to LR-4.

CONCLUSION

Ancillary features can cause category adjustment in a substantial proportion of LI-RADS observations. Adjustments tend to upward, are more common in MRI than CT, and predominantly affect observations categorized LR-3 based on major features.

CLINICAL RELEVANCE/APPLICATION

Ancillary features cause a substantial proportion of LR-3 observations to be upgraded to LR-4 , which is likely to affect management.

SSC05-05 Deep Convolutional Neural Network Applied to the Liver Imaging Reporting and Data System (LI-RADS) Category Classification: A Pilot Study

PURPOSE

To explore the performance of deep convolutional neural networks (CNN) for determining Liver Imaging Reporting and Data System (LI-RADS) category on multiphase dynamic contrast-enhanced CT and MRI.

METHOD AND MATERIALS

This study used a de-identified HIPAA-compliant dataset comprised of multiphase contrast-enhanced images for 329 unique hepatic observations (168 on CT and 161 on MRI) in JPEG format with corresponding diameters and consensus categories assigned by 2 members of the LI-RADS Steering Committee using LI-RADS v2013. A radiologist manually cropped the observations, including a margin of peri-observation parenchyma. Two CNNs were applied: 1) custom-made un-pretrained CNNs with quadruple-phase images (pre, arterial, portal venous, and delayed phases), and 2) transfer learning with pretrained networks with triple-phase images (pre, arterial and delayed phases). Each method used on-the-fly data augmentation technique. Lesion diameters were included, processed through a fully-connected neural network, and concatenated with the CNN models. The dataset was randomly split into training, validation, and test set at a ratio of 70: 15: 15. Accuracy and the area under receiver operating characteristic curve (AUROC) for classifying categories LR-1/2/3 versus LR-4/5/M were calculated on the test set.

RESULTS

Of 329 observations, 150 were LR-1/2/3 and 179 were LR-4/5/M; 229, 50, 50 observations were assigned to the training, validation, and test sets, respectively. Accuracy and the AUROC for the test set was 82% and 0.90 for transfer learning method, and 82% and 0.85 for custom-made method.

CONCLUSION

Deep learning CNN models show promise for categorizing hepatic observations according to LI-RADS on multiphase dynamic contrast-enhanced CT and MRI.

CLINICAL RELEVANCE/APPLICATION

Deep learning convolutional neural network models may provide a future platform for augmenting radiologists' interpretation of hepatic observations.

SSC05-06 Validation of Ultrasound Liver Imaging Reporting and Data System Version 2017 in Patients at High Risk for Hepatocellular Carcinoma

PURPOSE

To evaluate diagnostic performance of the Ultrasound Liver Imaging Reporting and Data System version 2017 (US LI-RADS v2017) for diagnosing hepatocellular carcinoma (HCC) in high risk patients with liver cirrhosis and to investigate association between US visualization score and US category.

METHOD AND MATERIALS

This study was approved by the institutional review board of our institution. A prospective surveillance study cohort included 407 cirrhosis patients at high risk for HCC who underwent US between December 2011 and March 2013. US LI-RADS category (1, 2, or 3) and US visualization score (A, B, or C) were assigned. The sensitivity and specificity for diagnosing HCC were calculated on the basis of per-patient and per-lesion, respectively, using contrast-enhanced CT, gadoxetic acid-enhanced MRI, and pathology as reference standards. The association between US visualization score and US category was evaluated using chi-squared test.

RESULTS

Of the 429 nodule in 407 patients, 32 nodules were confirmed as HCC in 28 patients. The sensitivity and specificity of US category 3 for diagnosing HCC on per-patient analysis were 34.4% (95% confidence interval [CI], 20.3-51.8%) and 92.2% (95% CI, 89.1-94.5%), respectively, and those on per-lesion analysis were 39.3% (95% confidence interval [CI], 25.7-54.8%) and 92.9% (95% CI, 89.8-95.1%), respectively. US visualization score was significantly associated with US category ($p = 0.04$), i.e., 11.9% (5/42) US category 3 showed score C, whereas 29.1% (111/381) US category 1 showed score C.

CONCLUSION

US LI-RADS v2017 category 3 demonstrated a high specificity, but a low sensitivity for diagnosing HCC in the surveillance of patients at high risk for HCC. US category assignment was significantly associated with US visualization score.

CLINICAL RELEVANCE/APPLICATION

The low sensitivity of US LI-RADS category 3 might be a limitation for the diagnosis of HCC in high risk patients, and it is related to the poor US visualization score.

SSC05-07 Accuracy of the LI-RADS v2017 Treatment Response Algorithm for Treated HCC

PURPOSE

To evaluate the accuracy of the LI-RADS v2017 Treatment Response algorithm for assessing viability of potential hepatocellular carcinomas that have been treated with transarterial embolization.

METHOD AND MATERIALS

This retrospective study was approved by the Institutional Review Board and was HIPAA compliant. The requirement for informed consent was waived. Histopathology reports and imaging studies of patients who had undergone transarterial tumor embolization and subsequent liver transplantation between 2006 and 2016 were reviewed. Three radiologists independently evaluated each patient's pre- and post-embolization imaging and assessed all lesions using the LI-RADS v2017 CT/MRI (pre-embolization) and Treatment Response (LR-TR, post-embolization) algorithms, and inter-reader agreement was calculated using Fleiss' Kappa. Radiology and histopathology reports were then correlated. Lesions were categorized based on histopathologic necrosis as either completely (100%) or incompletely (<=99%) necrotic, and performance characteristics for the LR-TR viable and nonviable categories were calculated for each reader.

RESULTS

45 patients with 64 histopathologically proven lesions were reviewed. Interreader agreement for pre-embolization category was moderate (k=0.57, 95% CI=0.45-0.71) and similar to agreement for LR-TR category (k=0.56, 95% CI=0.42-0.66). For predicting complete tumor necrosis, accuracy was moderate (0.66-0.70) and negative predictive value was very good (0.81-0.87). For predicting incomplete tumor necrosis, accuracy was moderate (0.59-0.64), and positive predictive value was very good (0.86-0.96). By consensus, 27% (17/64) of lesions were rated as LR-TR equivocal; 12 of these were incompletely necrotic.

CLINICAL RELEVANCE/APPLICATION

There are currently no published data that evaluate the performance of the LI-RADS Treatment Response Algorithm for predicting degree of locoregional therapy induced necrosis in individual lesions.

SSC05-08 Distinguishing Intrahepatic Cholangiocarcinoma from Hepatocelluar Carcinoma in Patients with and without Risks: The Evaluation of the LR-M Criteria of Contrast-Enhanced Ultrasound Liver Imaging Reporting and Data System Version 2017

lifei@sysucc.org.cn

PURPOSE

To assess the diagnostic performance of the LR-M criteria of Contrast-Enhanced Ultrasound Liver Imaging Reporting and Data System version 2017 (CEUS-LIRADS v2017) for differentiating intrahepatic cholangiocarcinoma (ICC) from hepatocellular carcinoma (HCC) in patients with and without risks (i.e. cirrhosis or chronic hepatitis).

METHOD AND MATERIALS

54 ICC in patients with risks and 55 ICC in patients without risks, and matched control cases of HCC with and without risks (n=59 and n=55, respectively) were enrolled. The wash-in-washout patterns of ICC and HCC lesions on CEUS were retrospectively analyzed according to the LR-M criteria of CEUS-LIRADS v2017. The diagnostic performances were assessed by receiver operating characteristic (ROC) curve analysis.

RESULTS

Peripheral rim-like hyper-enhancement, early washout (<= 30 or 60seconds), marked washout did not differ between ICCs with and without risks, while all of these features were more common in ICCs than in HCCs (P < 0.05) no matter the risk factors. Using the LR-M criteria of CEUS-LIRADS v2017 to differentiate ICC from HCC, the area under the ROC curve (AUC), sensitivity, specificity and accuracy were 0.92, 97.25%, 87.72% and 92.38%, respectively. If onset of early washout were adjusted to <= 30 seconds and onset of marked washout were adjusted to <= 4 minutes, the specificity was significantly increased to 95.61% (P = 0.021), while the AUC, sensitivity and accuracy didn't significantly change (P > 0.05). The rate of HCCs misdiagnosed as ICCs would decrease from 12.3% to 5.3%.

CONCLUSION

The LR-M criteria of CEUS-LIRADS v2017 showed feasibility in distinguishing ICCs from HCCs in patients with and without risks. After adjustment, specificity was significantly increased.

CLINICAL RELEVANCE/APPLICATION

The LR-M criteria of CEUS-LIRADS v2017 could not only be used for distinguishing ICCs from HCC in patients with risk but also without risks. Adjustment of current criteria could reduce the rate of HCC being misdiagnosed as ICC.

SSC05-09 ACR Ultrasound LI-RADS: Clinical Predictors of Diagnostic Adequacy for HCC Screening

PURPOSE

Sonographic screening for hepatocellular carcinoma (HCC) may be limited by parenchymal heterogeneity and other factors. ACR Ultrasound Liver Reporting and Data System (US LI-RADS) Version 2017 uses visualization scores to reflect these limitations. The purpose of this study is to evaluate distribution and predictors of visualization scores.

METHOD AND MATERIALS

In this retrospective, multicenter, HIPAA-compliant, IRB-approved study, patients at 5 sites had undergone screening US from Jan-Sep 2017 and US LI-RADS visualization scores were assigned on a clinical basis. Ultrasound reports and patient records were retrospectively reviewed.

RESULTS

2050 patients at risk for HCC (1078 men and 972 women; mean age 57.7) were included. Most common indications were cirrhosis (n=1054; 51.3%), non-cirrhotic HBV (n=555; 27.1%), and non-cirrhotic HCV (n=234; 11.4%). Most common etiologies of cirrhosis were HCV (n=396; 19.4%), alcohol (n=194; 9.5%), and HBV (n=187; 9.2%). 10.3% (n=212) patients had ascites. US LI-RADS scores had been assigned by 69 different readers. 42.7% of studies were read by women and 57.3% by men, with mean 19.3 years of experience and 40.3% of clinical time on US. Visualization scores were: A (No or minimal limitations) in 76.8% (n=1575); B (Moderate limitations) in 18.9% (n=388); and C (Severe limitations) in 4.2% (n=87). Reader experience (p=.37) and clinical time on US (p=.76) were not associated with impaired visualization scores in univariate analysis. In multivariate logistic regression analysis, the clinical diagnosis of cirrhosis (OR 3.6), NASH as etiology of cirrhosis (OR 2.0), ascites (OR 1.4), and male radiologist gender (OR 1.5) were associated with moderate or severe limitations.

CONCLUSION

US LI-RADS visualization scores in over 2000 patients demonstrated <5% of exams were severely limited and <20% were moderately limited. Clinical diagnosis of cirrhosis and NASH as etiology of cirrhosis were the strongest independent predictors of moderate to severe limitations in visualization in multivariate analysis.

CLINICAL RELEVANCE/APPLICATION

Although most US screening exams for HCC are diagnostically adequate, clinical diagnosis of cirrhosis and NASH as etiology of cirrhosis are associated with limited visualization.

PURPOSE

To compare the accuracy of 2D-SWE, MRE and TE for the diagnosis of fibrosis in patients with biopsy-proven NAFLD.

METHOD AND MATERIALS

In this IRB-approved study, 62 adult subjects (36F; 26M; age, 50±13 years; BMI, 35±7 Kg/m2) with biopsy-proven NAFLD were prospectively recruited. The distribution of fibrosis was as follow: F0=1; F1=17; F2=20; F3=15; F4=9. Subjects underwent a 2D-SWE which uses the comb-push technique (GE LOGIQ E9, GE Healthcare), MRE (2D-GRE; GE Healthcare) and TE (Fibroscan, Echosens) within one year of the biopsy. Area under the receiver operator curve (AUROC) and 95% confidence interval (CI) for the corresponding liver stiffness measurements (LSM, expressed in kPa) were calculated using as outcome significant (F>1) and advanced (F>2) fibrosis. Pairwise comparisons of AUROCs were conducted using the DeLong test. Statistical significance was set at $p<.05$.

RESULTS

Valid LSM were obtained in 57/62 subjects with 2D-SWE and in 59/62 subjects with TE. MRE was completed in 59/62 cases. Valid LSM measurements for all three techniques were available in 54/62 subjects. The AUROCs (95% CI) of 2D-SWE, MRE and TE were .796 (.673-.918), .847 (.744-.950), .766 (.638-.893) for significant fibrosis respectively and .890 (.803-.976), .950 (.887-1.00), .861 (.769-.953) for advanced fibrosis respectively. Pairwise comparisons revealed no statistically significant difference for significant (2D-SWE vs. MRE, p=.43; 2D-SWE vs. TE, p=.31; MRE vs. TE, p=.05) and advanced fibrosis (2D-SWE vs. MRE, p=.34; 2D-SWE vs. TE, p=.29; MRE vs. TE, p=.05).

CONCLUSION

2D-SWE, MRE and TE showed high accuracy for the diagnosis of advanced fibrosis in NAFLD with no significant difference at pairwise comparison.

CLINICAL RELEVANCE/APPLICATION

2D-SWE and TE are valid alternative to MRE for the diagnosis of advanced fibrosis in patients with NAFLD.

PURPOSE

To evaluate the diagnostic accuracy and cut-off values of full field-of-view tomoelastography stiffness maps of the liver in patients with hepatic fibrosis. We investigated novel multifrequency magnetic resonance elastography (mMRE) with piezoelectric driver and tomoelastography processing pipeline.

METHOD AND MATERIALS

In this prospective monocentre study, a total of 43 patients and 16 healthy volunteers underwent mMRE on a 1.5-Tesla MRI scanner (Magnetom Aera, Siemens Healthineers, Erlangen, Germany) using a piezoelectric driver and fast single-shot 3D wave-field acquisition at drive frequencies of 35, 40, 45, 50, 55 and 60 Hz. Acquisition parameters for each frequency were as follows: 9 slices, 8 time steps, 3 components, 256 x 256 matrix, 3 × 3 × 5 mm resolution and 2 averages. For patients, liver biopsy or definite morphological signs of cirrhosis were used as reference standard. Patients showed a wide range of chronic liver diseases including chronic hepatitis B and C, primary sclerosing cholangitis, nonalcoholic steatohepatitis and autoimmune hepatitis. Optimal cut-off values using the Youden-Index, area under the receiver-operating-characteristic-curve (AUROC), sensitivity and specificity were calculated accounting for compound multifrequency maps as well as single frequencies.

RESULTS

Mean values of mMRE shear wave speed (± standard deviation) of the liver across the entire cohort for 35, 40, 45, 50, 55, 60 and 35-60 Hz were 1.60 ± 0.29, 1.69 ± 0.37, 1.78 ± 0.43, 1.85 ± 0.49, 1.88 ± 0.51, 1.92 ± 0.54 and 1.77 ± 0.43 m/s, respectively. Tomoelastography stiffness maps showed high spatial resolution and anatomical details. E.g., 60-Hz cut-off values, AUROC values, sensitivity and specificity were as follows: fibrosis stage F>=1, 1.62 m/s, 0.92, 0.88 and 0.94; F>=2, 1.78 m/s, 0.93, 0.75 and 1.00; F>=3, 1.82 m/s, 0.97, 0.85 and 0.97; F4, 1.85 m/s, 0.98, 1.00 and 0.88.

CONCLUSION

Tomoelastography cut-off values show an excellent diagnostic accuracy for staging hepatic fibrosis. High-resolution stiffness maps enable the display of shear wave speed-related anatomical details including multiple organs such as liver and spleen.

CLINICAL RELEVANCE/APPLICATION

mMRE-based tomoelastography might reduce the need for invasive liver biopsies and indicate the distribution of fibrosis within the entire liver.

SSC06-03 Preoperative Liver Function Reserve Assessment and Future Liver Remnant Function Prediction in HCC patients with Gd-EOB-DTPA enhanced MRI: One-Stop Process

Monday, Nov. 26 10:50AM - 11:00AM Room: N229

mqhuang0702@163.com

PURPOSE

Our aim is to determine the feasibility of preoperative Gd-EOB-DTPA enhanced MRI in quantitative assessment of liver function reserve and prediction of post-hepatectomy liver function in HCC patients.

METHOD AND MATERIALS

This study enrolled 133 HCC patients who underwent Gd-EOB-DTPA enhanced MRI and indocyanine green (ICG) tests before surgery. The liver volume(LV) and mean liver T1 relaxation time before (T1pre) and after (T1pos) contrast was measure with T1pos and LV were measured in Hepatobiliary phase (HBP) scaned 20 minutes after injection. Virtual hepatectomy was processed in 3D images with resection plan defined by multi-disciplinary team discussion and adjusted by surgery record. Remnant T1pre, T1pos and LV were measured in virtual hepatectomy. The T1 reduction rate T1% [(T1pos- T1pre)/ T1pre], functional liver volume

(FV=LV*T1%), functional liver volume to weight ratio (FV/W) and T1 relaxation time to liver volume ratio (T1pos/LV) were calculated, the same as the remnant T1%, rFV, rFV/W, rT1pos/LV and rFV%. Correlations between functional parameters (T1pre, T1pos, T1%,FV, FV/W, T1pos/LV) and ICG reduction rate (ICG-R15), ALBI grade were investigated. Child-Pugh score was evaluated in postoperative day 5. The differences of remnant function reserve parameters between Child-Pugh A group and B&C group were analyzed. Multiple Logistic regression test was used to find the possible predictor for postoperative hepatic insufficient.

RESULTS

Those function liver volume parameters T1pos, T1%, FV, FV/W, T1pos/LV (mean value: 248.4msec, 64.12%, 786.38ml, 12.75ml/Kg, 0.21msec/ml) have shown statistical significantly correlation with ICG-R15 (rho=0.275, -0.290, -0.446, -0.398, 0.438; p<0.001). In predicting preoperative ICG-R15>14%, the cut-off value of FV, FV/W and T1pos/LV were 682.8ml, 10.80ml/kg, 0.236msec/ml, with sensitivity of 73.5%, 74.4%, 81.3%, specificity of 75.0%, 75.0%, 76.9%, respectively. Preoperative measured rFV% was the only positive factor in predicting post-hepatectomy Child-Pugh B&C hepatic insufficiency with cut-off value of 0.683, sensitivity of 71.43% and specificity of 58.67%.

CONCLUSION

Quantitative function liver volume in Gd-EOB-DTPA enhanced MRI can provide 'one-stop process' assessment of liver function reserve and prediction of post-hepatectomy liver insufficient.

CLINICAL RELEVANCE/APPLICATION

This research provide a 'one-stop process' assessment for HCC surgical plan

SSC06-04 Accuracy of Liver Surface Nodularity Score on CT for Staging HCV Hepatic Fibrosis: A Multi-Institutional Study

Monday, Nov. 26 11:00AM - 11:10AM Room: N229

andrewdennissmith@uabmc.edu

PURPOSE

To assess the accuracy of the Liver Surface Nodularity (LSN) score on CT and FIB4 score for staging hepatitis C virus (HCV) hepatic fibrosis.

METHOD AND MATERIALS

For this IRB-approved HIPAA-compliant retrospective multi-institutional observational study, adult patients with HCV chronic liver disease and a random liver biopsy obtained with 6 months of a liver CT were included. Participating institutions (N=5) each submitted de-identified data and liver CT images from 40 consecutive patients (N=200 total patients) centrally to a core lab. A REDCap web-based database was used to capture demographics, lab values, and the Scheuer stage of fibrosis (F0-F4) on biopsy specimens. Patients with insufficient information for Scheuer staging of fibrosis (N=3) and CT images that could not be processed (N=4) were excluded. The LSN score was measured using custom software in the final cohort (N=193), while blinded to clinical data. The patients age and serum labs (ALT, AST and platelets) were used to calculate the FIB4 score, a method for assessing liver fibrosis severity. The accuracy for differentiating the various stages of liver fibrosis using the LSN score, FIB4 score, and a combination were assessed with ROC analysis and AUC.

RESULTS

193 patients (69 females / 124 males; mean age 54 years) had Scheuer fibrosis stage: F0-F1 (N=36), F2 (N=41), F3 (N=47), and F4 (N=67). LSN scores increased with higher stages of liver fibrosis (mean: F0-F1=2.2±0.3, F2=2.4±0.4, F3=2.4±0.3, F4=3.2±0.9; p=0.001). For differentiating significant fibrosis (>=F2), advanced fibrosis (>=F3), and cirrhosis (>=F4), the AUCs for the LSN score were 0.88, 0.82, and 0.89, for the FIB4 score were 0.87, 0.87, and 0.91, and for both combined were 0.90, 0.87, and 0.93, respectively.

CONCLUSION

The combination of LSN score on CT and FIB4 score was highly accurate at staging HCV hepatic fibrosis in a multi-institutional study.

CLINICAL RELEVANCE/APPLICATION

The LSN score on CT and FIB4 score are easy to obtain and could be used to noninvasively and accurately stage hepatic fibrosis in patients with HCV chronic liver disease.

PURPOSE

To evaluate hepatic extracellular volume fraction (fECV) measurement using equilibrium CT images compared with both functional hepatic reserve that is assessed with 99mTc-diethylenetriamine-pentaacetic acid-galactosyl human serum albumin (GSA) scintigraphy, and liver fibrosis that is assessed with histopathological findings.

METHOD AND MATERIALS

A total of 86 patients (M/F=63/23; mean age, 67±13 years) who underwent routine dynamic liver CT and GSA scintigraphy for the clinical workup of hepatocellular carcinoma (n=74) and liver metastasis (n=12) were retrospectively studied. Absolute enhancement (in Hounsfield units) of the liver parenchyma (Eliver) and portal vein (Eblood) 3 minutes after contrast agent administration was measured on precontrast and equilibrium phase images. The fECV was calculated as the following equation: fECV(%) = Eliver x (100 - hematocrit(%)) / Eblood. Functional hepatic reserve was assessed with hepatic uptake ratio (LHL15) on GSA scintigraphy. Correlation between fECV and LHL15 was analyzed by the Spearman correlation coefficient. In 52 patients who underwent hepatectomy following the CT and GSA scintigraphy examinations, the fECV measurements were compared with the histopathological results of liver fibrosis staging ([F0-F4]: F0, absent of fibrosis; F4, severe fibrosis).

RESULTS

The fECV measurements showed a significant correlation with LHL15 ($r=-0.58$, $p<0.0001$). With an fECV threshold of 30.0%, the sensitivity and specificity for detecting reduced functional hepatic reserve (LHL15 < 0.91) was 90.5% and 86.2%, respectively. The areas under the ROC curve (AUC) of fECV for differentiating between normal and altered LHL15 was 0.90. The fECV measurements in F4 liver (30.4±4.3%) were significantly higher than that in both F0-1 (25.6±2.7%, $p=0.0004$) and F2-3 (26.9±3.1%, $p=0.02$), while no significant difference in fECV between F0-1 vs. F2-3 ($p=0.45$) was observed. With an fECV threshold of 28.8%, the sensitivity and specificity for differentiating between F0-3 and F4 was 75.0% and 77.5%, respectively. The AUC of fECV for F0-3 vs. F4 was 0.80.

CONCLUSION

Hepatic fECV measured with equilibrium CT imaging is associated with functional hepatic reserve and severity of liver fibrosis.

CLINICAL RELEVANCE/APPLICATION

Routine contrast-enhanced CT including equilibrium phase image may provide a means of assessing functional hepatic reserve and liver fibrosis.

SSC06-06 Comparative Diagnostic Accuracy of Ultrasound Shear-Wave Elastography and Magnetic Resonance Elastography for Classifying Fibrosis Stage in Adults with Biopsy-Proven Nonalcoholic Fatty Liver Disease

PURPOSE

There is limited data on the comparative accuracy of ultrasound (US) shear-wave elastography (SWE) and magnetic resonance elastography (MRE) for classifying fibrosis stage in nonalcoholic fatty liver disease (NAFLD). This study compares the diagnostic accuracy of SWE and MRE for classifying fibrosis stage in adults with NAFLD.

METHOD AND MATERIALS

This was an IRB-approved, HIPAA-compliant, prospective study of 46 adults (mean age 52 years; 25 women; mean body mass index [BMI] 32 kg/m2) with suspected NAFLD who from May 2016 to February 2018 underwent clinical liver biopsy followed by contemporaneous MRE and SWE for research. Fibrosis stage was scored (Nonalcoholic Steatohepatitis Clinical Research Network system). Receiver operating characteristics (ROCs) were assessed for SWE and MRE classification of dichotomized fibrosis stages (fibrosis stages >=1, >=2, >=3, and = 4) and the Youden index was used to select the corresponding thresholds. DeLong test was performed to compare the areas under the ROC curves (AUCs) of MRE and SWE pairwise.

RESULTS

Patients had the following fibrosis stages on histology: 0: 17; 1: 18; 2: 6; 3: 2; 4: 3. AUCs for SWE and MRE were 0.70 (95% confidence interval [CI], 0.55-0.85) and 0.83 (95% CI, 0.72-0.95), 0.77 (95% CI, 0.60-0.93) and 0.97 (95% CI, 0.92-1.00), 0.92 (95% CI, 0.82-1.00) and 0.93 (95% CI, 0.78-1.00), and 0.93 (95% CI, 0.84-1.00) and 1.00, for detecting fibrosis stage >=1, >=2, >=3, and =4, respectively. The differences were significant (p=0.02) for detecting fibrosis stage >=2 but not otherwise (p>=0.11). Youden-based SWE- and MRE-cutoffs for classifying stages >=1, >=2, >=3, and =4 with sensitivities/specificities were 8.67 kPa (45%/88%) and 2.29 kPa (69%/88%), 9.19 kPa (55%/89%) and 2.75 kPa (91%/97%), 8.67 kPa (100%/76%) and 4.19 kPa (80%/100%), and 9.40 kPa (100%/88%) and 5.04 kPa (100%/100%).

CONCLUSION

In adults with suspected NAFLD, clinically indicated biopsy, and low a priori probability of advanced fibrosis, SWE showed modest accuracy for detecting stage >= 1 or >= 2 fibrosis and high accuracy for detecting advanced (stage >=3) fibrosis. MRE may be more accurate than SWE at classifying fibrosis but greater power is needed to achieve significance.

CLINICAL RELEVANCE/APPLICATION

In adults with suspected NAFLD, SWE may have utility as an initial screen for advanced fibrosis. MRE may be required to reliably detect earlier stages of fibrosis.

SSC06-07 The Optimal Measurement Number of Shear Wave Elastography (SWE) for >=F2 Liver Fibrosis Diagnosis: Percentage of Color Filling Index (PCFI) Stratification Analysis using Automated Image Quality Analysis

Monday, Nov. 26 11:30AM - 11:40AM Room: N229

li.qian@mgh.harvard.edu

PURPOSE

To explore the optimal and minimum number of SWE measurements for >=F2 fibrosis considering measurement variability and diagnostic accuracy.

METHOD AND MATERIALS

Prospectively collected adult patients who underwent SWE before non-focal liver biopsy in three years. 10 SWE measurements

were performed for each patient at the identical biopsy locations (Segment 8) by one experienced sonographer before the biopsy. Fibrosis stages were evaluate using METAVIR criteria (F0-F4). The optimal and minimum measurement number for >=F2 were analyzed: (1) for each measurement number (1-9), correlated median SWE estimates were obtained using a nested bootstrap simulation; (2) ROC curves, and the associated AUROC values, were estimated using each set of SWE measurements (e.g., 2-10 measurements); (3) steps (1) and (2) were repeated 1000 times to obtain empirical distributions of median SWE estimates, and AUC estimates. Two variation parameters were evaluated, including (1) intra-subject SWE variation (m/s): the absolute median difference between individual SWEs and median SWE, and (2) interval width difference (IWD): the width differences of AUC 95%CI between a measurement number (1-9) and 10. A subgroup of patients with >=50% PCFI images (percentage of valid SWE pixels over the entire SWE image box, a metric for SWE image quality assessment) were also selected.

RESULTS

245 cases were enrolled (mean 48.5±13.2 yr; men 109, women 136), with the fibrosis stages F0=93, F1=92, F2=27, F3=23, F4=10. The intra-subject variation of the median SWE estimate decreased from 3.12 to 0.46m/s in 1-10 measurements in overall patients (n=245), and decreased from 3.74 to 0.37 in images with >=50% PCFI (n=106). we didn't detect AUC differences between measurement numbers 1-9 and 10, but IWD, which represents the variation of diagnostic accuracy, dramatically increased when measurements number =50% group, depending on the clinicians desired precision of IWD (within 0.040 units).

CONCLUSION

Current results demonstrated that, for >=F2 fibrosis diagnosis, the minimum SWE numbers may be reduced to 7 in overall images, and 6 when >=50% PCFI was applied for image quality control.

CLINICAL RELEVANCE/APPLICATION

Automated image quality analysis may have the potential to reduce the SWE measurements number for liver fibrosis diagnosis, thus improving the scanning process and diagnostic performance of SWE.

SSC06-08 Hepatic Shear Wave Elastography: Correlation Between Liver Stiffness and Esophagogastric Varices

PURPOSE

To evaluate the role of liver stiffness measurement (LSM) measured by shear wave elastography (SWE) in predicting the presence of esophagogastric varices (EGV) in patients with portal hypertension and to determine the correlation between the LSM and endoscopic grade of EGV.

METHOD AND MATERIALS

This study included 331 patients with chronic liver disease being evaluated for portal hypertension and planned for esophagogastroduodenoscopy. SWE was performed in the right lobe of the liver by using a convex broadband probe on GE LOGIQ E9 ultrasound machine. The shear wave liver stiffness (in kPa) was recorded at ten locations and the median values calculated. Endoscopic findings were interpreted with reference to the presence of varices and grade of the varices. Correlation between LSM and grade of varices was analyzed with the Pearson correlation coefficient. Multiclass Receiver operating characteristic (ROC) curves were constructed, and the area under the ROC curves (AUC) was calculated to determine the discriminating power between the grades of the varices.

RESULTS

LSM and variceal grade showed no significant correlation (R = 0.351286, P <0001). The AUC for detection of the presence of varices was 0.7259. The AUC for differentiating between various grades of the varices was 0.6470, 0.5802, 0.6259 and 0.7692. Box plot of the LSM and grade of varices revealed no discrimination power. Hepatic shear wave stiffness was marginally useful in predicting the presence of varices. But the discriminating power of LSM among the grades of varices was poor.

CONCLUSION

We found marginal utility of LSM in predicting the presence of EGV. However, contrary to the existing knowledge, in our study, we found no correlation between liver stiffness measurement and grade of EGV. The liver stiffness measurement is not a reliable predictor of portal hypertension.

CLINICAL RELEVANCE/APPLICATION

In advanced fibrosis, liver stiffness measurements in isolation does not seem to predict the clinical severity of portal hypertension. The additional assessment of splenic stiffness should be considered.

SSC06-09 Diagnostic Accuracy of Combination of Quantitative Point Shear Wave Elastography (pSWE) and Serum Markers for the Assessment of Fibrosis in Patients with Chronic Liver Disease Using Liver Biopsy as the Reference Standard

ChengFang@nhs.net

PURPOSE

To evaluate individual and combined diagnostic performance of quantitative point shear wave elastography (pSWE) and serum markers for the assessment of liver fibrosis in patients with chronic liver disease.

METHOD AND MATERIALS

This prospective study received ethics approval, and all participants provided written informed consent. Shear wave speed (SWS) using pSWE (VTQ) and serum fibrosis markers (aspartate aminotransferase-to-platelet ratio index [APRI], King's score) were measured in 169 consecutive patients with chronic liver disease (mixed aetiology). Receiver-operating characteristic (ROC) analysis were performed to evaluate the diagnostic accuracy of their individual and combined performance in predicting significant (F>=3) and severe/cirrhosis (F>=5) liver fibrosis using ISHAK histologic fibrosis stages (F0-6) as reference. Cut-off values were determined using Youden Index. Spearman's correlation coefficient between the SWS, fibrosis marker and fibrosis stage were calculated.

RESULTS

Ishak histology stages were 0-2 (n=90, 53%), 3-4 (n=50, 30%), 5-6 (n=29, 17%). There was a good correlation between SWS, King's score, APRI and the Ishak stage (ρ=0.682, ρ=0.632 and ρ=0.584, respectively, P <= .001). The areas under the ROC curves (AUROC) for SWS, King's score, and APRI, were 0.86, 0.87, and 0.89 for the diagnosis of significant fibrosis (F>=3) and 0.98, 0.79, and 0.85 for the diagnosis of severe fibrosis/cirrhosis (F>=5), respectively. pSWE is superior than APRI (P=0.0005) and King's score (P=0.002) in predicting severe fibrosis/cirrhosis (F>=5), The optimum pSWE cut-off values for significant and severe fibrosis/cirrhosis were 1.22 and 1.86 m/s, respectively. The AUROC for combining the serum fibrosis marker and pSWE in diagnosing significant fibrosis were 0.93, outperforming using pSWE alone (P=0.0048).

CONCLUSION

pSWE is superior than serum markers in predicting severe fibrosis/cirrhosis is and comparable to serum markers for significant fibrosis. Combining pSWE and serum markers improves the diagnostic accuracy in predicting significant fibrosis.

CLINICAL RELEVANCE/APPLICATION

pSWE has excellent diagnostic accuracy for predicting cirrhosis. In addition, combining pSWE and serum markers significantly improve the diagnostic performance of significant fibrosis.

PURPOSE

Although a renal mass can have imaging features of a typical clear cell renal cell carcinoma (ccRCC) on CT, up to 30% of these are found to be benign after surgery, most commonly oncocytoma (ONC). The purpose of our study was to develop a machine learning-based renal lesion classifier using open source Google TensorFlow™ Inception (TCI) Machine Learning to discriminate ccRCC from ONC on four-phase CT.

METHOD AND MATERIALS

With IRB approval and HIPAA compliance, we derived a cohort of 176 patients with 195 lesions (131 patients with 125 ccRCCs; 61 patients with 49 ONC) with preoperative four phase (unenhanced (UN), corticomedullary (CM), nephrographic (NP), excretory (EX)) CT imaging. Regions of interest were drawn around the tumor on every slice in each phase to create a 3D tumor volume. To preprocess the DICOM data into a format currently supported by TCI, 3D tumor data was extracted in the x, y and z plane and converted into a red, green and blue (RGB) jpeg image using the three color channels to encode each slice. 70% of the data was used in the training set and 30% in the testing set. We investigated several approaches to convert the data into a set of 2D JPEG images that adequately represented each tumor and were used to train the final layer of the neural network model.

RESULTS

When we analyzed 3 mid-slices of the tumor in the x, y and z plane in each post contrast phase, the EX phase had the highest accuracy in classifying both ccRCC (79.6%) and Onc (59.5%) compared to the accuracy in the CM (ccRCC=78.3%, Onc=46%) and NP (ccRCC=77.2%, Onc=46.5%) phases. The highest accuracy in classifying ccRCC was obtained by submitted all x,y and z planes in all phases as one image to TCI with an accuracy of 82.5%, however this lowered the correct classification of Onc to 52.2%.

CONCLUSION

In this pilot study, TCI enabled independent classification of clear cell RCC from oncocytoma on a four phase MDCT with an accuracy of 82.5%.

CLINICAL RELEVANCE/APPLICATION

A TCI based method if developed and validated prospectively may be an adjunct to radiologists for discrimination between clear cell RCC and Oncocytoma on multiphasic CT minimizing diagnostic uncertainty and enabling more accurate patient triage.

SSC07-03 Differentiation of Renal Cell Carcinoma and Oncocytoma Using Machine Learning-Based MR Radiomics

PURPOSE

To build a random forest predictive model for distinguishing between renal cell carcinoma (RCC) and oncocytoma that integrates clinical, preoperative, and multimodal automated features.

METHOD AND MATERIALS

Forty-one patients with histologically confirmed renal tumors (23 RCCs; 18 oncocytomas) were identified from a single institution. Two experts (HL and DP), with 23 and 10 years of experience of reading body MR respectively, blinded to the histologic diagnoses, made image diagnosis based on the preoperative MR images (T2-weighted and T1-contrast enhanced sequences). Histogram, geometric and texture features were extracted from preoperative MR images. Using a random forest algorithm, automated features were integrated with clinical data to generate a multivariate predictive model. Receiving operating characteristic curves (ROCs) and areas under the curve (AUCs) were used to assess model performance by using the Delong method for statistical comparison of ROCs.

RESULTS

Patients with oncocytoma had higher mean age than patients with RCC (65.8± 7.7 vs. 58.7 ± 11.4 years, p=0.022). Tumor size did not differ significantly between RCC and oncocytoma (average of 2.3 ± 0.9 vs. 2.5±1.0cm; p = 0.620). For each patient, 5 clinical features and 10566 automated features were included in the model. After feature reduction, 32 features remained. This included 30 T1-contrast enhanced features and 2 T2-weighted features. The tested model achieved accuracy of 80.5% (AUC = 0.80) with sensitivity of 82.6% and specificity of 77.8%. Shape Volume-Compactness (T1C), NGTDM-Busyness (T1C), GLSZM-ZSV (T1C), and Shape Volume-Volume (T2WI) were the features contributing most to the model. Compared to our model, expert 1 achieved accuracy of 63.4% (AUC = 0.59; p = 0.019) with 95.7% sensitivity and 22.2% specificity, and expert 2 achieved accuracy of 57.5% (AUC = 0.55; p = 0.005) with 65.2% sensitivity and 44.4% specificity.

CONCLUSION

Preliminary results using machine learning algorithms demonstrated improved accuracy in differentiation of RCC and oncocytoma when compared with expert interpretation. Further validation is needed in a larger cohort.

CLINICAL RELEVANCE/APPLICATION

Oncocytoma, a benign tumor, that cannot typically be distinguished from RCC based on routine clinical imaging. A machine learning based approach with high accuracy would potentially spare patients unnecessary surgery, ablation, and biopsy.

SSC07-04 The Utility of Radiomic Features in Differentiation of Clear Cell Renal Cell Carcinoma from Non-Clear Cell Renal Cell Carcinoma: A Preliminary Study

Monday, Nov. 26 11:00AM - 11:10AM Room: S503AB

kimonlee@163.com

PURPOSE

To investigate the ability of radiomic features derived from the corticomedullary phase images to differentiate clear cell renal cell carcinoma (RCC) from non-clear cell RCC.

METHOD AND MATERIALS

This study involved 450 patients with 463 tumors histopathologically diagnosed as clear cell RCC (n=362), papillary RCC (n=54) or

chromophobe RCC (n=47), whose corticomedullary phase images were available. To conduct the study, 80% (n=371) and 20% (n=92) tumors were randomly selected as development and validation cohorts keeping the ratio of clear cell RCC to non-clear cell RCC consistent. Using the development cohort, a discriminative subset from 1023 radiomic features was selected by SVM with LASSO regularization. Receiver operating characteristic analysis was conducted to assess the predictive ability of the selected CT radiomic features in differentiation of clear cell RCC from non-clear cell RCC in the validation cohort. For contrast, a radiologist, with 6 years of experience in genitourinary imaging, was instructed to predict the subtypes (clear cell or non-clear cell RCC) of the validation cohort. The chi-square test was conducted to compare the accuracies between the SVM model and the radiologist.

RESULTS

Our research demonstrated that the SVM model combining 15 features was strongly discriminative in differentiation of clear cell RCC from non-clear cell RCC in the validation cohort. The sensitivity, specificity, overall accuracy, and area under the curves for the SVM model in the validation cohort were 84.7% (61/72), 85% (17/20), 84.8% (78/92), and 0.905, while the sensitivity, specificity, and overall accuracy for the radiologist were 94.4% (68/72), 60% (12/20), and 86.9% (80/92). According to the chi-square test, there was no statistically significant difference between the accuracies of the SVM model and the radiologist (p=0.672).

CONCLUSION

This study demonstrated that CT radiomic features derived from the corticomedullary phase images can aid in the differentiation of renal cell carcinoma subtypes, which is comparable to experienced radiologists.

CLINICAL RELEVANCE/APPLICATION

The effective SVM model combining 15 radiomic features could help the clinical management of patients with renal cell carcinoma, especially patients with non-clear cell renal cell carcinoma.

SSC07-05 Differentiation of Renal Lipid-Poor Angiomyolipoma from Renal Cell Carcinoma by Machine Learning Based on Whole-Tumor Texture Features of Three-Phase CT Images

Monday, Nov. 26 11:10AM - 11:20AM Room: S503AB

cem2008@163.com

PURPOSE

To determine the diagnostic performance of machine learning in the differentiation of lipid-poor angiomyolipoma (lp-AML) from renal cell carcinoma (RCC) based on whole-tumor quantitative texture features of three-phase CT images.

METHOD AND MATERIALS

A total of 40 patients with 41 pathologically proven lp-AML and 95 patients with 97 pathologically proven RCCs were included by this retrospective study. All patients underwent three-phase CT study which consisted of precontrast phase (PCP), corticomedullary phase (CMP) and nephrographic phase (NP). Texture features were extracted from whole-tumor images at three-phase, single PCP, CMP and NP, respectively. Then support vector machine with recursive feature elimination method based on five-fold cross-validation (SVM-RFECV) were utilized to establish the discriminative classifiers. The performance of classifiers based on three-phase, single PCP, CMP and NP were determined and compared with each other. The performance of machine learning classifier in the differentiation of lp-AML from RCC was compared with morphological interpretation by radiologists using Receiver operating character (ROC) analysis.

RESULTS

43, 34, 24, 20 features subset were extracted as candidate features in three-phase, PCP, CMP and NP by Boruta package for python respectively. Among of these, 13, 24, 9 12 optimal feature subset further screened by SVM-RFECV entered to establish machine learning classifier in the differentiation of lp-AML and RCC. The classifier base on three-phase whole tumor images achieved the best performance in discriminating lp-AML from RCC, with the highest accuracy, area under curve (AUC), sensitivity, and specificity of 92.78%, 0.96, 92.78% and 92.78%, respectively. The performance of morphological interpretation by radiologist was inferior to machine learning classifier in differentiating lp-AML and RCC, with lower accuracy, AUC, sensitivity and specificity of 69.57%, 0.66, 36.59% and 89.69%.

CONCLUSION

Machine learning classifier based on whole-tumor texture features from three-phase images could reach more accurate discrimination between lp-AML and RCC than conventional morphological interpretation.

CLINICAL RELEVANCE/APPLICATION

Machine learning classifier is more powerful than morphological interpretation by radiologists and is recommended as part of a MR study prior to renal tumor removal.

SSC07-06 Is Dual-Energy CT (DECT) Of Renal Masses Ready For Prime Time? Diagnostic Accuracy of Conventional Attenuation Change and Iodine Concentration Thresholds at Rapid-kVp-Switch DECT for Detection of Enhancement in Renal Masses

Monday, Nov. 26 11:20AM - 11:30AM Room: S503AB

nschieda@toh.on.ca

PURPOSE

Iodine concentration (i[]), measured on DECT, is an alternative to attenuation difference (ΔHU) for diagnosis of enhancement in renal masses. Reported i[] thresholds vary and may be too high to detect enhancement in hypoenhancing papillary renal cell carcinoma (pRCC). This study re-evaluates rapid-kVp-switch DECT i[] thresholds for diagnosis of enhancement in SRMs.

METHOD AND MATERIALS

With IRB approval, we evaluated 34 renal masses (including 9 pRCC) diagnosed histologically and 30 benign cysts with renal mass protocol rapid-kVp-switch DECT between 2015-2017. A blinded Radiologist measured i[] (mg/mL) and ΔHU. Enhancement was defined as: 1) i[]>2 mg/mL (Marin et al., Kaza et al.) 2) i[]>1.6 mg/mL (Zarzour et al.) and 3) ΔHU>20 HU. Diagnostic accuracy was tabulated and compared by ROC analysis.

RESULTS

There were no differences in age, gender or size of lesions between groups (p>0.05). Using i[]>2.0 mg/mL achieved sensitivity/specificity/Area under ROC curve (AUC) of 73.3%/100%/0.87. 23.5% (8/34) pRCCs were misclassified as non-enhancing with i[] ranging from 0.7-1.6 mg/mL. Using i[]>1.2 mg/mL, sensitivity/specificity/AUC of 86.7%/100%/0.93 was achieved. 11.8% (4/34) pRCCs were misclassified as non-enhancing with i[] range from 0.7-0.9 mg/mL. Using ΔHU>20 HU achieved sensitivity/specificity/AUC of 93.3%/94.1%/0.94. 5.9% (2/34) pRCCs were misclassified as non-enhancing and 6.7% (2/30) cysts were misdiagnosed as enhancing due to pseudoenhancement. There was no difference in AUC comparing the three methods for detecting enhancement (p>0.05), with higher false negatives encountered with i[] and false positives encounterd with ΔHU.

CONCLUSION

Published iodine concentration thresholds for enhancement in renal masses measured at DECT result in substantial false negative results among hypoenhancing papillary RCC, with the 1.2 mg/mL threshold outperforming 2.0 mg/mL. ΔHU is more sensitive for detection of enhancement compared to iodine concentration but with higher false positive results due to pseudoenhancement.

CLINICAL RELEVANCE/APPLICATION

ΔHU remains a robust method to diagnose enhancement in renal masses and is more sensitive for detection of low level enhancement in papillary tumors compared to published iodine concentration values; however, DECT remains valuable for diagnosis of pseudoenhancement.

SSC07-07 The Reality of Dual-Energy CT Iodine Quantification in High-Attenuating Renal Lesion: A Comparison to Standard Hounsfield Units Attenuation

Daniele Marin, MD, Durham, NC (*Abstract Co-Author*) Research support, Siemens AG

PURPOSE

To determine if dual-energy CT (DECT) derived iodine quantification allows accurate characterization of indeterminate high-attenuating renal lesions, and to identify technique- and patient-related variables that may influence lesion characterization.

METHOD AND MATERIALS

220 patients with 265 high-attenuating renal lesions (mean attenuation 54 33HU; 83 malignant lesions) were included in this retrospective IRB-approved, HIPAA-compliant study. Each patient underwent a single-energy unenhanced CT followed by nephrographic phase DECT using four different state-of-the-art DECT platforms (two rapid-kV-switching DECT [rsDECT] systems and two dual-source DECT systems [dsDECT]). Quantitative iodine concentration values and conventional enhancement (ΔHU) were calculated for each lesion. Receiver operating characteristics area under the curve (AUC) for renal lesion characterization were determined. To calculate diagnostic accuracy, surgical resection with histological workup, biopsy, and imaging follow-up for >24 months were used to determine the final category. Receiver operation characteristics, with dedicated area under the curves (AUC) were calculated to differentiate malignant from benign renal lesions. Nominal logistic regression analysis was performed to identify technique- and patient-related variables that may influence lesion characterization.

RESULTS

Diagnostic accuracy for lesion characterization was significantly higher using ΔHU (AUC: 0.93 with an optimal cut-off of 20HU), compared to iodine concentration values (AUC: 0.83; p<0.0001). Optimal iodine concentration thresholds were significantly different for the rsDECT system (2.0mg/ml with AUC of 0.84) compared to the dsDECT system (1.0mg/ml with an AUC of 0.87) (p<0.0001). Using the dedicated iodine thresholds resulted in 32 false positive findings and 20 false negative findings. Lesion location relative to the dual-energy field of view, patient size and DECT platform did not demonstrate any effect on lesion characterization.

CONCLUSION

Conventional measurements of enhancement yield statistically significant higher accuracy compared to iodine concentration measurements for the characterization of indeterminate high-attenuating renal lesions.

CLINICAL RELEVANCE/APPLICATION

Conventional measurements of enhancement is statistically significantly superior to iodine concentration measurements in the characterization of indeterminate high-attenuating renal lesions.

SSC07-08 Clinical Evaluation of Virtual Unenhanced Images from Second-Generation Dual-Energy CT Gemstone Spectral Imaging

Monday, Nov. 26 11:40AM - 11:50AM Room: S503AB

Awards
Student Travel Stipend Award

Participants
Jennifer Xiao, MD , Seattle, WA (*Presenter*) Nothing to Disclose
Janet M. Busey, MS, Seattle, WA (*Abstract Co-Author*) Nothing to Disclose
David A. Zamora, MS, Seattle, WA (*Abstract Co-Author*) Nothing to Disclose
Achille Mileto, MD, Seattle, WA (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

jmxiao@uw.edu

PURPOSE

To assess virtual unenhanced (VUE) images from a second-generation dual-energy CT gemstone spectral imaging (GSI) technology and to evaluate how measured attenuation compares to that from true unenhanced (TUE) images.

METHOD AND MATERIALS

Our single-center, retrospective study was IRB-approved and HIPAA-compliant. Fifty-seven subjects (32 men, 25 women; mean age, 65 years) underwent a contrast-enhanced CT of the abdomen on a second-generation dual-energy CT GSI technology with fast kV switching (80/140 kV) between September 2017 and March 2018 for hematuria work-up (n=42) and renal mass evaluation (n=15). TUE images were acquired in all cases in single-energy mode at 120 kV. TUE and VUE images were reconstructed at a slice thickness of 2.5 mm. Attenuation values of liver, pancreas, kidneys, adrenal glands, psoas muscle, subcutaneous fat, aorta, IVC, and main portal vein were measured on TUE and VUE images. In addition, attenuation values were obtained from 24 patients with renal mass (cystic, n=5; solid, n=19). Number of renal stones detected on TUE and VUE were also recorded. Data were analyzed using a Student paired t-test.

RESULTS

There was no significant difference in measured attenuation between TUE and VUE images throughout the abdomen (P>.05, for all comparisons). Mean attenuation values from solid and cystic renal lesions were not significantly different (TUE: 18.4 HU and 9.8 HU vs. VUE: 18.6 HU and 8 HU; P=.76 and P=.38, respectively). We observed a significant difference in number of detected renal stones between TUE (n= 21) and VUE (n= 12) images (P=.01).

CONCLUSION

VUE images obtained from contrast-enhanced data acquired on a second-generation dual-energy CT with GSI technology represent a good approximation of TUE images for noncontrast evaluation of abdominal organs and focal renal lesions. Nevertheless, our preliminary data indicate that a considerable number of small renal stones may not be detected.

CLINICAL RELEVANCE/APPLICATION

Prospective implementation of VUE images may render opportunities for decreased radiation exposure in multi-phase abdominal CT protocols for evaluation of genitourinary pathology.

SSC07-09 Clinical Decision Algorithm for the Evaluation of Renal Cystic Lesions Using Single-Phase Split-Filter Dual-Energy CT

Monday, Nov. 26 11:50AM - 12:00PM Room: S503AB

Participants
Aurelio Cosentino, MD, Torino, Italy (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

Markus.Obmann@usb.ch

PURPOSE

To evaluate the diagnostic performance of single source split-filter dual energy CT (tbDECT) to exclude enhancement in renal cystic lesions at venous phase abdominal CT.

METHOD AND MATERIALS

A total of n=230 simple or minimally complicated renal cysts were identified in n=51 consecutive patients who underwent both abdominal tbDECT and magnetic resonance (MR) examination; the latter was used as the 'gold standard' to classify the cysts as Bosniak I or Bosniak II. Material decomposition images were processed off of venous phase series and regions of interest (ROI) were placed within each cystic lesion, blindly to MR. For each ROI, four parameters were assessed simultaneously (Virtual Unenhanced attenuation values [HU], contrast enhancement attenuation values [HU], iodine density [mg/dl] and ROI size [cm2]) to test different approaches for lesion characterization. Renal cysts were considered as not enhancing if contrast enhancement (CM) <= 10 HU and iodine density (IOD) <= 0.5 mg/dl. The ROI was considered small if size <= 0.2 cm2.

RESULTS

Using MR n=207 Bosniak I and n=23 Bosniak II cysts were identified. At virtual unenhanced images, 48% of the cysts were not hypodense (> 10 HU). Both CM and IOD alone gave high percentages of pseudoenhancement (false positive 47% and 33% respectively). The combination of criteria (IOD first then CM) improved specificity to 79%. Exclusion of small ROIs reduced false positives to 3%. An algorithm for the exclusion of enhancement, combining all the criteria, was created.

CONCLUSION

The combined evaluation of multiple criteria provided by tbDECT correctly characterizes Bosniak I and II renal cysts as not enhancing, reduces false positive findings and potentially avoids unnecessary work-ups. We propose an algorithm that can be easily implemented in clinical practice.

CLINICAL RELEVANCE/APPLICATION

Excluding enhancement in renal cystic lesions with 97% of specificity, applying an easy to use algorithm on single-phase dual-energy images from single source, split-filter twin-beam dual-energy CT.

djdisantis@gmail.com

PURPOSE

To analyze the multiple choice questions (MCQ) in three years of *Radiology* CME exercises with regard to: adherence to accepted MCQ question-writing tenets comportment with the journal's own 'CME Question Writing Guideline' for its authors.

METHOD AND MATERIALS

308 multiple choice questions in *Radiology* CME exercises from 2015 through 2017 comprised the test group. They were analyzed by the three authors for: adherence to standard, validated question-writing tenets, such as those promulgated by the American Board of Radiology compliance with the 'CME Question-Writing Guideline' provided by the journal to its authors Test items that violated the question-writing tenets/guidelines were designated as flawed.

RESULTS

Of the 308 questions, 174 (56%) contained from one to four item-writing flaws. The most frequent flaws were: an unfocused question stem a negative question stem heterogeneous answer options. The adherence to guidelines in the CME examinations varied widely, ranging from zero flawed items, to 10 of 10 flawed items. There was no pattern of improvement over the time frame of the study.

CONCLUSION

In our specialty's most prestigious journal, more than half of the self-assessment CME questions do not follow standard, validated question-writing tenets, and do not comport with the journal's own guidelines for its authors.

CLINICAL RELEVANCE/APPLICATION

Our results should prompt a relook at the process of *Radiology*'s self-assessment CME exam creation, and in particular opportunities for author training to bolster test validity.

For information about this presentation, contact:

krakhra@toh.ca

PURPOSE

To determine whether a quantitative model for evaluating research productivity and distributing research salary awards with protected time increased the publication productivity of an academic radiology department.

METHOD AND MATERIALS

A metrics based, research protected time (RPT) model awarding research salary awards with protected time was designed through a tripartite consensus process between the Departmental Academic Chair, Faculty Radiologists and Radiologist practice plan, first implemented in January 2010. A retrospective analysis was performed tabulating all unique PubMed indexed publications by Department Faculty members between January 1, 2003 and December 31, 2017 by calendar year. The annual publication productivity for the Department was compared between the non-RPT period (January 1, 2003 to December 31, 2009) and RPT-period (January 1, 2010 to December 31, 2017), in absolute numbers and also normalized to the radiologist FTE (full time equivalent) count. A sub-analysis of those faculty members who had both RPT and non-RPT status years during the period of evaluation was also performed comparing the productivity between the two statuses. Statistical analsyis employed paired t-test, with level of significance set at 0.05. The proportion of publications from those in the RPT program was calculated.

RESULTS

There was significantly greater annual departmental publication productivity in the RPT versus the non-RPT periods, in absolute numbers (75.1 vs 18.4, p=0.007) and also when normalized to FTE count (1.55 vs 0.50, p=0.004). Twenty-three faculty members were identified as having both RPT and non-RPT years during the period of evaluation. There was significantly higher mean annual publication productivity during their RPT versus their non-RPT years (5.1 vs 1.3, p=0.011). On average, 62% of annual unique publications were from faculty members with RPT, although the RPT faculty members comprised only 26% of the overall faculty membership.

CONCLUSION

The implementation of the RPT program with funded protected time led to a significant increase in departmental publication productivity. At the individual level, faculty members' productivity was significantly greater during the years in which they received RPT.

CLINICAL RELEVANCE/APPLICATION

Models of funded research time with quantitative measure of publication output should be considered in academic departments wishing to increased their publication productivity.

Jay R. Parikh, MD, Houston, TX (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

amykpatel64112@gmail.com

PURPOSE

To assess early-career radiologists' satisfaction with their professional mentorship, as well as to gain insights into the design of future mentorship programs.

METHOD AND MATERIALS

A 10-question survey was distributed by email in September 2017 to a random sample of 2,000 practicing radiologists who are members of the Young and Early-Career Professionals Section (YPS), which includes radiologists who are either under age 40 or within their first 8 years of practice. The survey was designed by the ACR YPS Executive Committee and the ACR Commission for Women and Diversity. Survey questions addressed respondents' satisfaction with their current mentorship and preferences for subsequent mentorship opportunities.

RESULTS

Responses included 51% male, 49% female; 37% academic, 35% private practice, 14% hospital employed. 69% responded that their practice did not have a formal mentoring program. Of those with a formal mentoring program, 47% were not satisfied with the program, and an additional 21% were only somewhat satisfied. 44% of respondents reported having no mentor, and 21% had a single mentor. 78.09% responded that having a mentor would be valuable, very valuable, or extremely valuable. A mentor was described as extremely valuable by 39% of women, vs. 14% of men. Having a mentor of the same gender was described as extremely or very valuable by 44% of women vs. only 5% of men. When asked what are the most valuable characteristics of a mentor, the highest rated options were: (1) greater level of experience, (2) same subspecialty, (3) same practice type, and (4) national reputation. Respondents felt overall more strongly that mentors be able to serve as advocates for career growth outside of, rather than within, the mentee's own institution.

CONCLUSION

Early-career radiologists commonly lacked a formal mentor or were unsatisfied with their mentor, and strongly desired greater mentorship opportunities; women radiologists more strongly expressed this desire. Radiologists generally desired an experienced mentor of a similar subspecialty and practice type who could facilitate their growth beyond the local institution.

CLINICAL RELEVANCE/APPLICATION

More robust mentorship programs are needed to combat burnout, promote job satisfaction, and foster the professional development and career success of the next generation of radiologists.

Honored Educators

SSC08-04 May I Please Speak with the Radiologist: Introducing First Year Radiology Residents to Their Consultant Role

Monday, Nov. 26 11:00AM - 11:10AM Room: S104A

Participants
Karla A. Sepulveda, MD, Houston, TX (*Presenter*) Nothing to Disclose
Marc H. Willis, MMM,DO, Houston, TX (*Abstract Co-Author*) Investor, Resonea

For information about this presentation, contact:

kasepulv@bcm.edu

PURPOSE

An education portal with case vignettes of common clinical scenarios a first year radiology resident may be consulted on was created to assist in the transition to their new role as consultants on appropriate imaging ordering. The portal emphasizes concepts of evidence based imaging utilization, patient safety and patient centered care.

METHOD AND MATERIALS

A web based education portal with 20 vignettes of common clinical scenarios seen in an emergency room was created. Residents were asked to select the most appropriate imaging for the given clinical history. The questions incorporated clinical decision support technology with integrated ACR Appropriateness Criteria to provide evidence based recommendations for imaging indications. Radiation safety, IV contrast and cost questions were also included. The module ended with 2 open ended questions asking learners how they would manage clinical scenarios requiring interactions with referring clinicians, patients, and patient's family. The 12 residents participated in the pilot during their first week of residency. Following an introductory lecture highlighting concepts of high value, patient-centered care, residents took the self directed module in a virtual classroom. Residents then returned for a debrief session that included a patient discussing her perspective on radiologist communication, review of the responses to the open ended questions, and a qualitative post-assessment.

RESULTS

The portal was well received. 90% of participants believed the module should be included in an introductory curriculum for radiology residents. 80% thought the patient centered cases and patient discussion helped them to be more aware of the patient perspective. The majority of the residents reported increased comfort level in consultation regarding appropriate imaging, IV contrast, radiation exposure, cost of imaging and patient safety following the module.

CONCLUSION

A web based education module with integrated clinical decision support is an innovative approach to introducing first year radiology residents to their new role as consultants on high quality appropriate imaging. The portal reinforces imporant medical education concepts and encompasses multiple ACGME competencies.

CLINICAL RELEVANCE/APPLICATION

High value, patient-centered care can be emphasized with incoming first year radiology residents by a web based education module with integrated clinical decision support.

SSC08-05 The "Look Ahead" Technique: A Novel Way to Engage Medical Students in the Reading Room with Minimal Disruption to the Preceptor's Workflow

Monday, Nov. 26 11:10AM - 11:20AM Room: S104A

Participants
Jennifer Huang, MD, Greensboro, NC (*Presenter*) Nothing to Disclose
Brian Bingham, MD, Nashville, TN (*Abstract Co-Author*) Nothing to Disclose
Martin I. Jordanov, MD, Nashville, TN (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

j.huang002@gmail.com

PURPOSE

Engaging medical students during a Radiology course can be challenging. We sought a way to actively engage students with live cases, allow them to interact with the PACS workstation, and experience what it is like to be a radiologist. This educational model has not been studied before.

METHOD AND MATERIALS

All medical students enrolled in Diagnostic Radiology or Medical Imaging and Anatomy course at our institution between May 2016 and June 2017 were eligible. The "Look Ahead" technique is as follows: during a routine read-out, a preceptor identifies several non-urgent imaging studies and allows the students to look at the images first and make their own findings and conclusions. When ready, the students present their findings, discuss the case, and observe the preceptor generate a final report. Students were emailed a post-course survey to compare the "Look Ahead" technique with the current standard (observing a preceptor interpret imaging studies with accompanying teaching points).

RESULTS

Thirty-four (56.7%) of 60 potential respondents completed the post-course survey. Of these 34 students, 24 (70.6%) reported at least one reading room case (mean 4.6) in which they had the opportunity to employ the technique with a mean of 2.4 unique preceptors. When compared to the current standard (0=not to 100=very interested/engaged/valuable/memorable), the 'Look Ahead' technique was associated with increased student-reported interest (92.5 vs 75.1, $p<0.01$), engagement (94.0 vs 70.3, $p<0.01$), educational value (92.5 vs 73.2, $p<0.01$), memorability of the case (88.5 vs 73.2, $p<0.01$) and of teaching points made by the preceptor (90.1 vs 76.7, $p<0.01$). All students agreed that compared to the current standard, the 'Look Ahead' technique increased their confidence in reviewing and interpreting imaging studies.

CONCLUSION

The findings suggest that students benefit significantly from the 'Look Ahead' technique, with increased interest, engagement, educational value, and memorability. The potential benefits warrant further investigation on a grander scale, with greater faculty and student involvement. It would be interesting to investigate if there are any longer term effects of this technique on student performance or career choice.

CLINICAL RELEVANCE/APPLICATION

The "Look Ahead" technique of medical student instruction in the radiology reading room promotes active student engagement with minimal disruption to the preceptor's workflow.

SSC08-06 Beyond Cadaveric Dissection: Through Virtual Dissection, Radiology Adds Educational Value to Medical Undergraduate Anatomy Education

Monday, Nov. 26 11:20AM - 11:30AM Room: S104A

Awards
Trainee Research Prize - Resident

Participants
Kathryn Darras, MD, Vancouver, BC (*Presenter*) Education Advisory Committee, Sectra AB
Rebecca Spouge, Vancouver, BC (*Abstract Co-Author*) Nothing to Disclose
Anique de Bruin, Maastricht, Netherlands (*Abstract Co-Author*) Nothing to Disclose
Jeroen van Merrienboer, Maastricht, Netherlands (*Abstract Co-Author*) Nothing to Disclose

Rose Hatala, Vancouver, BC (*Abstract Co-Author*) Nothing to Disclose
Bruce B. Forster, MD, Vancouver, BC (*Abstract Co-Author*) Stockholder, Canada Diagnostic Centres

PURPOSE

Virtual dissection is performed with CT scans on near life-size anatomy visualization tables, which function like touchscreen PACS workstations. Students work together to manipulate the data and perform their dissection. The purpose of this study was to develop and qualitatively assess the educational value of virtual dissection laboratories for first year medical students as well as to understand students' preferred pedagogical approaches for learning from this new technology.

METHOD AND MATERIALS

Following IRB approval, all first year medical students were included in this study (n = 292). A Basic Virtual Dissection Curriculum focused on normal anatomy was offered to all students concurrently with their cadaveric laboratories and an extra-curricular Advanced Virtual Dissection Curriculum focused on pathology was offered to interested students. 36.6% of students participated in this Advanced Curriculum. Following the sessions, students were surveyed to determine their attitude toward virtual dissection and the pedagogical approaches they perceived to be the most useful for learning with this technology. Results were statistically analyzed using the Schulze method.

RESULTS

Student response rate was 69.2% for the Basic Curriculum and 82.9% for the Advanced Curriculum. 93.1% indicated that virtual dissection was 'definitely' a valuable addition to the anatomy lab. 88.5% of respondents 'agreed' or 'strongly agreed' that virtual dissection improved their understanding of disease and 94.2% of students 'agreed' or 'strongly agreed' that it improved their understanding of the role of the radiologist in patient care. Students reported that the aortic aneurysm case was the most memorable case because the imaging made it easier to understand the pathogenesis of the disease. Students felt that small group demonstration and problem-based learning would be the best teaching approaches for this technology.

CONCLUSION

Virtual dissection adds value to medical undergraduate anatomy teaching by increasing students' understanding of the clinical relevance of anatomy. Students' preferred pedagogical approaches for learning from this technology were small group demonstration and problem based-learning.

CLINICAL RELEVANCE/APPLICATION

Virtual dissection is a new technology that can be used provide formal radiology teaching to medical students and thereby increase their awareness of the speciality.

SSC08-07 Evidence of Gender Bias in Recommendation Letters for Women in Radiology: Are We There Yet?

Monday, Nov. 26 11:30AM - 11:40AM Room: S104A

Participants
Alejandra Duarte, MD, New York, Colombia (*Abstract Co-Author*) Nothing to Disclose
Jenny T. Bencardino, MD, Lake Success, NY (*Presenter*) Nothing to Disclose
Christine M. Glastonbury, MBBS, San Francisco, CA (*Abstract Co-Author*) Author with royalties, Reed Elsevier

Mauricio Castillo, MD, Chapel Hill, NC (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

jenny.bencardino@nyumc.org

PURPOSE

To evaluate for gender bias language used in recommendation letters written for women trainees and faculty seeking to be hired in academic or clinical positions, promotion or professional society membership

METHOD AND MATERIALS

109 letters written by 4 senior academic radiologists (1 man, 3 women) were independently assessed by 2 reviewers. The quality of the letters was scored using the University of Arizona Commission on the Status of Women (UA CSW) guidelines. Positive 1 point qualifiers included: mention of research, mention of publications, more than 1 page length, use of adjectives that emphasize accomplishments and ability, and use of adjectives that denote leadership. Negative 1 point qualifiers included the use of adjectives that evoke gender stereotypes and emphasize effort, mention personal life, and express doubt. Using these guidelines, a ranking system was created with letters classified as excellent (4-5); very good (3-4); good(2-3); fair(0-2); and poor(<0). Other positive adjectives not included in the UA CSW were recorded. Positive1 point qualifier adjectives used more than 5 times in this collection of letters were added to a revised scoring system

RESULTS

The average score using the UA CSW guidelines was good (2.5). There was no significant difference between those letters written by the only male (56) versus female letter writers (53) (M: 2.5; W: 2.4). 81% mentioned publications while only 60% mentioned research involvement. 70% of letters contained adjectives that emphasized accomplishments and ability but only 17% used adjectives that denote leadership. In one-fifth of the letters, adjectives that denoted gender stereotype were used. When using a modified scoring system, the average score rose to very good (3.2). Again, no gender difference was noted between man (3.2) versus women (3.2) letter writers using the revised scoring system.

CONCLUSION

In our preliminary sample, gender bias language was found in 21% of the letters written for women by senior faculty members without distinction of the writer's gender. Only 60% mentioned research and only 14% included leadership qualifiers. We encourage academic faculty to keep handy guidelines to write persuasive and gender bias-free letters for their women trainees and colleagues.

CLINICAL RELEVANCE/APPLICATION

Based on preliminary results, we developed modified UA CSW guidelines that aim to help writing persuasive, gender-bias free letters for women radiologists.

charles.maxfield@duke.edu

PURPOSE

To evaluate for discrimination in radiology resident selection based on the physical appearance of the applicant.

METHOD AND MATERIALS

We carried out a simulated resident selection process utilizing deception of reviewers. Seventy-four core faculty (37 male and 37 female) from five academic radiology departments reviewed mock residency applications under the guise of resident application screening. Applications included demographic information and a photograph, representing a spectrum of facial attractiveness and

obesity, combined with randomized academic and supporting variables. Reviewers independently scored applications on their desirability for interview. Comparisons were made between reviewer scores and the application variables using linear mixed fixed and random effects models.

RESULTS

Reviewers evaluated 5447 applications (mean: 74 applications per reviewer). The applicant's facial attractiveness strongly predicted reviewer rating (attractive versus unattractive, B = 0.30 ± standard error 0.056); neutral versus unattractive, B = 0.13 ± 0.028). Obesity (versus not obese) was less influential but predictive of rating (B = -0.14 ± 0.024). Overall, United States Medical Licensing Examination Step 1 scores were the strongest predictor of reviewer rating (ß = 0.49 ± 0.030). Less influential but still significant predictors included preclinical class rank (B = 0.25 ± 0.040 for 1st vs. 3rd quartile), clinical clerkship grades (B = 0.23 ± 0.034 for top vs. bottom tertile), race/ethnicity (B = 0.25 ± 0.059 for black/Hispanic vs. white), and Alpha Omega Alpha membership (B = 0.21 ± 0.032). Using the 85th percentile of reviewer rating as a cutoff for projected interview selection, 90% of obese and facially unattractive applicants would be rejected, compared to only 76% of non-obese facially attractive applicants ($p<0.01$).

CONCLUSION

Our study provides evidence of discrimination against obese and facially unattractive applicants in admissions to radiology residency programs. Notably, obesity and facial attractiveness were as influential in the selection of applicants for interview as were well-established academic factors.

CLINICAL RELEVANCE/APPLICATION

Resident selection committees should invoke strategies to detect and manage appearance-based bias

SSC08-09 Structured Tool for Screening Candidates for Academic Neuroradiology Faculty Positions

Monday, Nov. 26 11:50AM - 12:00PM Room: S104A

Participants
Maria Braileanu, MD, Atlanta, GA (*Presenter*) Nothing to Disclose
Nadja Kadom, MD, Atlanta, GA (*Abstract Co-Author*) Nothing to Disclose
Mark E. Mullins, MD,PhD, Atlanta, GA (*Abstract Co-Author*) Nothing to Disclose

Elizabeth A. Krupinski, PhD, Atlanta, GA (*Abstract Co-Author*) Nothing to Disclose
Amit M. Saindane, MD, Decatur, GA (*Abstract Co-Author*) Nothing to Disclose
Brent D. Weinberg, MD, PhD, Atlanta, GA (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Interview selection of candidates for an academic radiology faculty position is variable and subject to unconscious biases, such as gender and race. The purpose of this study was to retrospectively apply a quantitative resume rubric as a screening tool to identify qualified candidates for an interview in the hiring process.

METHOD AND MATERIALS

All resumes from 2012 to 2017 for a total of 8 neuroradiology faculty positions at our institution were collected and anonymized. One blinded reviewer scored the resumes based on categories that included: education (board certification, medical school ranking, residency ranking, fellowship years, degrees), work experience (years), extracurricular experience (leadership, societies, committees, teaching, honors, volunteerism), and research (abstracts, oral presentations, manuscripts, chapters). Maximum total score was 24 points. The relationship between 1) resume score and interview status, and 2) resume score and job offer was examined using logistic regression. Non-parametric ROC analysis based on resume score and job offer was performed using STATA. This study was IRB exempted.

RESULTS

102 anonymized resumes were scored. The overall mean was 13.6±3.8 with a range of 5-22. A total of 17 interviews were conducted and 10 candidates were eventually offered a position. Higher resume score significantly increased the likelihood of an interview ($p=0.02$) but was not significantly associated with a job offer ($p=0.07$). The area under the curve in the ROC analysis for differentiating interview selection based on resume scoring was 0.69 (95%CI 0.56-0.82). At a cutoff of 14, the model is 82.4% sensitive, and 54.1% specific.

CONCLUSION

We demonstrated that standardized scoring of resumes as an initial screening tool in the hiring process is feasible. A higher resume score was associated with interview selection. This tool can potentially be applied in the future to reduce unwanted bias in the hiring process as it is neutral to factors such as gender and race.

CLINICAL RELEVANCE/APPLICATION

Standardized resume screening is feasible, with a higher score associated with interview selection in retrospective analysis, and may be applied in the future to reduce unwanted bias in the initial steps of the hiring process.

PURPOSE

Radiologists mark and measure significant image findings in their daily work to assess patients' conditions and therapy responses. These large-scale and diverse clinical annotations can be great data sources to train data-hungry algorithms (e.g. deep learning) for medical image analysis. However, they are basically unsorted and lack semantic annotations like the lesion type and location. We aim to organize and explore them by learning a deep feature embedding for each lesion. It can help us to 1) know their types and locations; 2) find similar lesions in different patients, i.e. content-based lesion retrieval; and 3) find similar lesions in the same patient, i.e. lesion matching across scans for disease tracking.

METHOD AND MATERIALS

We built a large-scale and comprehensive dataset, DeepLesion, by mining the PACS. It contains 32,735 lesions from 10,594 CT studies of 4,427 patients. The lesions are quite diverse, and include e.g. lung nodules, liver lesions, adenopathy, and bone lesions. The train/val/test sets have 70%, 15%, 15% of the data split in patient level. We learn a feature embedding for each lesion that keeps the similarity relationship of the type, location, and size, i.e. lesions with similar attributes should have similar embeddings. We get the lesion types and locations by label propagation and self-supervised body-part regression. Size is directly obtained from the radiological marking. A triplet network with a sequential sampling strategy is utilized to learn the embedding. The network is a multiscale multi-crop convolutional neural network that can exploit both context and detail of the lesion images. The learned embeddings can be applied in lesion retrieval and matching by nearest neighbor searching.

RESULTS

In the test set of DeepLesion, we achieve 91.5±0.1%, 92.8±0.0%, and 94.9±0.0% accuracy in lesion retrieval w.r.t. the lesions'

type, location, and size, respectively. The area-under-curve value for lesion matching is 95.9% in a manually labeled test set of 1313 lesions from 103 patients.

CONCLUSION

We proposed an algorithm to learn feature embeddings for a variety of lesions to encode their type, location, and size. Experiments showed its effectiveness in lesion retrieval and matching.

CLINICAL RELEVANCE/APPLICATION

The proposed algorithm can be used in content-based lesion retrieval and intra-patient lesion matching, which can help radiologists find similar lesions and track lesions in follow-up studies.

SSC09-03 Multi-Stage Deep Disassembling Networks for Generating Bone-Only and Tissue-Only Images from Chest Radiographs

CONCLUSION

Deep neural network based automatic disassembling network for CRs is demonstrated and its performance is validated by SSIM proving its potential to improve interpretability of CRs and aid pysicians for accurate diagnosis.

Background

Dual-energy subtraction technique produces bone-only and tissue-only images to improve interpretability of chest radiographs (CRs). However, the use of this technique was limited because it requires a specialized hardware device for capturing the CRs. In order to overcome this limitation, we developed a deep disassembling networks for CRs (DDCN) which generates bone-only and tissue-only images from a normal CR.

Evaluation

To develop DDCN, we collected a total of 617 CRs with both bone-only and tissue-only images, which were produced by dual energy subtraction technique. To clean the dataset, we excluded 100 cases with suboptimal image quality. Furthermore, we refined the remaining 517 cases using guided filter and non-local means filter to remove image noises. Subsequently, we randomly divided the 517 datasets into the training dataset (n=467) and validation dataset (n=50). We designed a novel two-stage deep convolutional network where the first-stage is designed for observing context of a CR and the second-stage is for producing bone-only and tissue-only images given the first-stage output. The network is constructed with residual architecture, 40 convolutions for the first-stage and 14 convolutions for the second-stage. We quantitatively measured the performance of our network using SSIM which measures the structure difference between a given ground truth image and our network-producing image. In validation dataset, the measured SSIM comparing ground truth tissue-only images and our network-producing results was 0.9678. When we limit the region of interest (ROI) as lung area, the SSIM was measured as 0.9835. In the case of bone-only image, it was 0.9877 and 0.9870 when we limit ROIs as whole image and lung area, respectively.

Discussion

DDCN produces bone-only and tissue-only images from CRs taken by conventional X-ray device. We believe it is the first introduction of deep neural network for disassembling bone and tissue from a CR.

SSC09-04 Non-invasive Tracking of Cancer Evolution using Deep Learning-Based Longitudinal Image Analysis

Monday, Nov. 26 11:00AM - 11:10AM Room: E450A

Participants
Yiwen Xu, PhD, Boston, MA (*Presenter*) Nothing to Disclose

Hugo Aerts, PhD, Boston, MA (*Abstract Co-Author*) Stockholder, Sphera Inc

PURPOSE

Tumors are continuously evolving biological systems, and medical imaging is uniquely poised to monitor those changes in patients, before, during, and after treatment. While it is trivial to track tumor lesions over space and time, it is much harder to develop models encompassing all the time points. Here we investigated the use of recurrent deep learning network capable of analysing time series CT images of locally advanced non-small cell lung cancer (NSCLC) patients.

METHOD AND MATERIALS

Dataset A consists of 179 stage III NSCLC patients treated with definitive radiation therapy (581 scans, mean 3.2 scans per patient). This dataset was separated into independent training/tuning (n=107), and test (n=72) cohorts. Transfer learning through convolutional neural networks (CNN) merged with a recurrent neural network was trained on serial scans. Survival was analyzed for a separate test set with AUC and Kaplan Meier curves. Further pathologic response validation of the CNN model was performed on Dataset B (n=79 patients, 158 scans, 2 per patient) treated with chemoradiation followed by surgery. This cohort was used to

validate pathological tumor response and compared to performance with volume change.

RESULTS

Enhanced performance on the test set was observed with the addition of each follow-up scan into the CNN model for 2-year survival (AUC=0.64, 0.69, 0.74, p<0.05), comporable results were demonstrated for one-year survival. The models with 3 follow-up scans showed strong stratification power for high and low risk groups of the predictions using Kaplan-Meier analysis (Log-rank, p<0.05). The hazard ratios for the one-year and 2-year survival models were 6.16 and 2.38, respectively (p<0.05). The CNN model significantly stratified pathological responders and cases of gross residual disease in Dataset B (AUC=0.65, p<0.05), with predictive results comparable to tumour volume change.

CONCLUSION

This study demonstrates promising results using deep learning to combine patient scans at multiple time points to improve clinical survival and response predictions. Pathologic validation of this biomarker was shown on an independent validation cohort.

CLINICAL RELEVANCE/APPLICATION

Tracking of cancer evolution using deep learning applied to medical imaging showed promising predictions of patient outcome and pathologic response, without the need for manual tumor contours.

SSC09-05 Interpretation of Computed Tomography Without Reconstruction: Reading Sinograms to Detect Intracranial Hemorrhage

Monday, Nov. 26 11:10AM - 11:20AM Room: E450A

chuang35@mgh.harvard.edu

PURPOSE

In the current medical practice, diseases or conditions, such as intracranial hemorrhage (ICH), are usually diagnosed using reconstructed images that are generated from sophisticated reconstruction algorithms. In this study, we explore the feasibility to directly detect ICH from non-contrast head computed tomography (CT) in data domain instead of image domain by applying deep learning techniques on CT sinograms.

METHOD AND MATERIALS

A total of 889 head CT examinations were retrieved from our institutional database, and each axial slice was annotated by 5 board-certified neuroradiologists. The pixel values of CT images were then converted into linear attenuation coefficients, upon which the 2D parallel-beam Radon transforms were applied to generate simulated sinograms. To investigate the effects of number of projection views and detector size on ICH detection, 3 sets of sinograms were produced: '360 x 729', '120 x 240' and '40 x 80', where 'm x n' means the sinogram obtained from m projection views and n detectors. The sinograms were then randomly splitted into training (635 cases), validation (127 cases) and testing (127 cases) sets, which were used to train, validate, and evaluate a convolutional neural network (CNN) that inputs a sinogram and outputs the probability of ICH. To improve generalization, data augmentation was used for training by applying affine transformations (translation, scaling, rotation and reflection) on CT image slices followed by Radon transforms. For comparison, another CNN was built and trained with reconstructed CT images.

RESULTS

The CNN model using CT images as inputs achieved 91.5% test accuracy on ICH detection, and the models using "360 x 729", "120 x 240" and "40 x 80" sinograms as inputs detected ICH with 80.2%, 78.1%, and 76.7% accuracy, respectively.

CONCLUSION

This study shows the potential of direct detection of ICH using CT raw data without image reconstruction. The results also suggest the possibility of using sparse projection views and large-size detectors without sacrificing the ICH detection accuracy, which could lower the radiation dose and equipment costs.

CLINICAL RELEVANCE/APPLICATION

Direct detection of critical conditions like ICH using sinograms without image reconstruction will save the processing time that is critical in situations like emergency rooms. The potential of radiation dose and equipment cost reduction is also of interest to radiologists.

SSC09-06 Image Annotation by Eye Tracking: Accuracy and Precision of Centerlines of Obstructed Small Bowel Segments Placed Using Eye Trackers

PURPOSE

To determine the accuracy and precision of centerlines of obstructed small bowel segments placed using eye trackers.

METHOD AND MATERIALS

This HIPAA-compliant IRB-approved retrospective pilot study included seven subjects diagnosed with small bowel obstruction (SBO) by CT. For each subject, an obstructed segment of bowel was chosen. Three observers then annotated the centerline of the segment with three methods: manual fiducial placement or visual fiducial placement using either a Tobii x3-120 or 4c eye tracker, which report the location on the screen at which an observer is looking. This location was mapped to 3D coordinates within the CT volume using a custom 3D Slicer module. Each annotation was repeated three times. The distance between centerlines was calculated after alignment using dynamic time warping (DTW) to account for the variable number of fiducials placed. Intra-observer DTW distance between manual and visual centerlines was calculated as a measure of accuracy. Intra- and inter-observer DTW distances between centerlines placed with each method were calculated as measures of precision. One-sample t-tests were performed to assess whether mean DTW distances were less than 1.5 or 3 cm for each measure of accuracy or precision respectively.

RESULTS

DTW distances between manual and visual centerlines ranged from 1.1±0.2 to 1.8±0.2 cm, and were significantly less than 1.5 cm for two of three observers using both visual methods ($P<0.01$). Intra- and inter-observer DTW distances for manual centerlines were 0.6±0.1 and 0.8±0.2 cm, and for visual centerlines ranged from 1.0±0.4 to 1.9±0.6 cm, but were less than 3.0 cm in all cases ($P<0.01$).

CONCLUSION

Eye trackers may be used for visual annotation of the centerlines of obstructed small bowel segments with accuracy and precision that compare favorably to the threshold diameter of 3 cm for diagnosis of SBO on CT. Accuracy varied among observers, but precision was consistently favorable.

CLINICAL RELEVANCE/APPLICATION

SBO is a common and important disease, for which machine learning tools have yet to be developed. Image annotation is a critical first step in machine learning, but manual annotation of small bowel is prohibitively time-consuming. Image annotation by eye tracking is sufficiently accurate and precise relative to the diameter of obstructed small bowel to serve as a potential first step in the development of machine learning tools that facilitate diagnosis of SBO on CT.

SSC09-07 Big Data Interpretability: Automatically Identify Mislabeled Data in Medical Imaging Deep Learning

Monday, Nov. 26 11:30AM - 11:40AM Room: E450A

PURPOSE

In big data applications, data quality and variations can significantly influence performance of deep learning models. Manual labeling or natural language processing-based labeling inevitably generates some mislabeled data. We developed a dedicated method for deep learning to automatically identify potentially mislabeled data.

METHOD AND MATERIALS

We proposed a novel algorithm framework using entropy loss and influence functions to measure data's relevance and correlation strengths with respect to classification performance in convolutional neural network (CNN) models. We identified a clinically-acquired digital mammographic imaging data and their BI-RADS breast density categories (a/b/c/d). Category a (fatty) and d (extremely dense) each has 350 images, while Category b (scattered fibroglandular density) and c (heterogeneously dense) each has 2,000 images. We implemented a CNN-based binary classification model on distinguishing Category a vs d and another similar model for Category b vs c. We did two experiments: 1) Before training models, we purposely flipped the labels for 10% randomly selected data in each category and used our method to identify those flipped data; and 2) We ran our method on the original un-flipped data to identify those potentially mislabeled images by radiologists and evaluate the effect by using a published scheme that assesses the "correctness" of clinically-assigned BI-RADS breast density categories.

RESULTS

The AUC is 0.99 and 0.96 for the Category a vs d model and for the Category b vs c model, respectively. For experiment 1), our method can identify 98% of the purposely flipped data in Category a and d, and 92% in Category b and c, by automatically examining as small as only 30% of the full dataset. For experiment 2), there is 78% (or 96%) overlap in the potentially mislabeled data between those identified by our method and those specified by the "correctness" assessment method, by examining 50% (or 90%) of the full dataset.

CONCLUSION

We developed an automated method for deep learning and demonstrated it can identify vast majority of mislabeled data in the BIRADS-based clinical breast density assessment in digital mammograms.

CLINICAL RELEVANCE/APPLICATION

Fully-automated identification of mislabeled data for deep learning can significantly improve data quality, model's performance and reliability, as well as stratified data interpretability.

SSC09-08 Approaching Chest-CT-Level Performance on Chest X-Rays with Deep-Learning

Monday, Nov. 26 11:40AM - 11:50AM Room: E450A

PURPOSE

To determine whether deep learning algorithms can detect abnormalities on chest X-rays (CXR) before they are visible to radiologists.

METHOD AND MATERIALS

We trained deep learning models to identify abnormal X-rays and CXR opacities using a set of 1,150,084 chest X-Rays. We used a retrospectively obtained independent set of de-identified chest X-rays from patients who had undergone a chest CT scan within 1 day (TS-1, n=187), 3 days (TS-3, n=197) and 10 days (TS-10, n=230) of the X-ray to evaluate the algorithms' ability to detect abnormalities that were not visible to the radiologist at the time of reporting on the X-ray. Natural language processing algorithms were used to establish ground truth from radiologist reports of the CT scans, on 2 parameters - 'any abnormality' and 'hyperdense abnormality (HA)' - defined as any abnormal focal or diffuse hyperdense abnormality in the lung fields including but not limited to nodule, mass, fibrosis and calcification. The CT scans were used as ground truth to evaluate the accuracy of the original CXR report and the deep learning algorithms.

RESULTS

Of 187 CT scans in TS-1, 153 contained an HA. 52 of these (34%) had been picked up on the original CXR by the reporting radiologist, and 63 of these (41%) were picked up by the deep learning algorithm. Of 180 abnormal scans in TS-1, 106 (59%) had been picked up as abnormal on the original CXR by the reporting radiologist, and 120 of these (67%) were picked up by the deep learning algorithm. To detect HA, this amounts to an accuracy of 0.49, sensitivity of 0.41 and specificity of 0.85 for the algorithm, versus an accuracy of 0.44, sensitivity of 0.34 and specificity of 0.91 for the original radiologist read of the chest X-ray. To detect any abnormality, the accuracy, sensitivity, and specificity are 0.67,0.67 and 0.71 respectively for the algorithm, and 0.59,0.59 and 0.71 respectively for the reporting radiologist. Similar results were observed on TS-3 and TS-10, as shown in the figure below

CONCLUSION

Deep learning algorithms can pick up abnormalities that have been missed on chest X-rays but identified on a subsequent chest CT.

CLINICAL RELEVANCE/APPLICATION

Using deep learning algorithms to screen chest X-rays could result in higher sensitivity at identifying abnormal scans than currently possible, with only a small corresponding increase in the number of false positives.

SSC09-09 A Portable Automated X-Ray Imaging System and Reading Solution for Screening Lung Diseases

Monday, Nov. 26 11:50AM - 12:00PM Room: E450A

CONCLUSION

The AXIR system allows clinicians to save time and money while providing patients with good service at any location. The AI-based

automation facilitates its use as a screening and diagnosis tool, allowing doctors to make real-time decisions with high precision and reliability. The system, in the future, may cover other anatomical regions while the AI-engine can be enhanced to diagnose broader disease indications.

Background

A chest x-ray is a commonly used examination for screening and diagnosis of lung diseases. Artificial intelligence (AI) solutions, for automated image analysis, have been implemented as cloud-based solutions centered on hospitals with well-equipped infrastructures. However, two-thirds of the planet does not have access to radiology services due to lack of infrastructure and expertise. We have developed a portable automated X-ray imaging system and reading solution (AXIR) with embedded AI technology to solve this problem.

Evaluation

The AXIR system comprises of a low power portable generator (3kW), a wireless detector (resolution > 4lp/mm), an image pre-processing tool, an AI-based analysis engine, and a mobile viewer. The AI engine screens images for abnormalities and displays the location. Abnormalities can further be classified as pleural effusion, cardiomegaly, opacity, infiltrate, consolidation, fibrosis, hilar enlargement, and calcification. The AI models were trained using public datasets and with images acquired using the AXIR system. The system is being validated at a poor infrastructure site handling about 1000 chest X-rays / month. The performance of the system is evaluated by measuring the accuracy, sensitivity, and specificity of diagnosis.

Discussion

Access to diagnostic imaging services has a great impact on public health and can potentially increase, for example, early detection. AXIR's portable X-ray system with embedded AI-based analytics is a novel highly accessible medical device. In our initial test, we achieved a diagnostic accuracy of 92% with a sensitivity of 94% and specificity of 90%. At our pilot site, the system reduced the diagnosis time from an average of 3 days to less than 10 minutes and brought the patient re-visit rate down to 1% from 20%.

PURPOSE

Sarcopenia consists of loss of muscle mass and strength/function. As adipose tissue expands and muscle and bone tissue decrease with aging, there is a concomitant increase in proinflammatory and a reduction in anti-inflammatory factors contributory to chronic inflammation. We aimed to evaluate associations of several inflammatory markers with DXA-measured sarcopenia markers in a representative sample of European healthy adults aged 65-79 years.

METHOD AND MATERIALS

Baseline whole-body DXA scan was performed and fresh blood samples collected in 1122 participants enrolled in the NU-AGE trial, a one-year, multicenter, randomized, single-blind, controlled trial (NCT01754012) testing the effects of a dietary intervention. Appendicular lean mass (ALMI, lean mass from arms plus legs/height2) and skeletal mass index (SMI, lean mass from arms plus legs/weight) were used as DXA markers of sarcopenia. Quantitative determination of inflammatory markers was performed by ELISA. After a log-transformation of DXA parameters the Pearson Product-Moment Correlation was applied to test the associations between body composition and inflammation markers in both genders.

RESULTS

In male population, a positive association was found between ALMI and albumin (ρ=0.20; p < .05) and SMI and ghrelin (ρ=0.19; p < .05). A negative association was found between ALMI and adiponectin (ρ=-0.23; p< .001), while SMI was negatively correlated with leptin (ρ=-0.70; p<.001) and C-Reactive Protein(CRP) (ρ=-0.24; p<.001). In females, ALMI was positively associated with leptin (ρ=0.19; p<.01), and CRP (ρ=0.22; p<.01). SMI was positively associated with ghrelin (ρ=0.24; p<.001), while negatively with leptin (ρ=-0.62; p<.001), CRP (ρ=-0.23; p<.001), and AGP (ρ=-0.26; p<.001).

CONCLUSION

Sarcopenia correlates with an increase of inflammatory status in elderly. In males and females, SMI correlates positively with ghrelin, an anti-inflammatory molecule, and negatively with pro-inflammatory markers such as leptin, CRP and AGP; while ALMI showed ambiguous associations with inflammatory markers. Thus, SMI appears to be a better predictor of inflammatory risk status in the elderly.

CLINICAL RELEVANCE/APPLICATION

DXA-derived sarcopenia markers show a correlation with inflammatory markers useful to picture patients' risk status. SMI may predict inflammatory status better than ALMI; but further research is required.

SSC10-04 Automated Segmentation of Thoracic Paraspinous Muscles: Pipeline for Large-Scale Data Mining on CT

Monday, Nov. 26 11:00AM - 11:10AM Room: S102CD

Participants
Leon Lenchik, MD, Winston-Salem, NC (*Presenter*) Nothing to Disclose
Ryan T. Barnard, MS, Winston-Salem, NC (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

llenchik@wakehealth.edu

PURPOSE

To compare automated pipeline for thoracic paraspinous muscle segmentation with manual segmentation on chest CT examinations.

METHOD AND MATERIALS

Atlas-based automated pipeline for thoracic paraspinous muscle segmentation was developed using open-source medical image analysis tools: Advanced Normalization Tools (ANTs), the Oxford Centre for Functional Magnetic Resonance Imaging of the Brain Software Library (FSL), and the scikit-image Python image processing library. After the correct image at T12 level was identified, the left paraspinous muscle was automatically segmented and the muscle attenuation and cross-sectional area were recorded. Ground truth was obtained using 475 non-contrast chest CT exams by manually segmenting the left paraspinous muscle at T12 level with muscle thresholds set at -29 to +150 HU (Mimics software version 19.0; Materialise, Leuven, Belgium). The CT images are heterogeneous in field of view, voxel spacing, convolution kernel, scanner manufacturer and model, reconstruction algorithm, and image quality. Dice and Jaccard similarity indices were determined.

RESULTS

Compared to manual segmentation, the automated pipeline had a mean Dice index of 0.85 (SD=0.07) and a mean Jaccard index of 0.74 (SD=0.09). Mean accuracy error for muscle attenuation was 1.2 HU; range: 0-4.9 HU. Mean accuracy error for muscle cross-sectional area was 1.83 cm2; range: 0-9.3 cm2.

CONCLUSION

The automated pipeline for thoracic paraspinous muscle segmentation is sufficiently accurate to allow for large-scale data mining of heterogeneous chest CT images.

CLINICAL RELEVANCE/APPLICATION

Current CT image evaluation of sarcopenia requires manual segmentation, unrealistic for large datasets. The automated pipeline for sarcopenia evaluation on chest CTs could be adapted to other body regions including abdomen, pelvis, and extremities.

SSC10-05 Assessment of Sarcopenia on Computed Tomography (CT): A Systematic Review of Technical Parameters

Monday, Nov. 26 11:10AM - 11:20AM Room: S102CD

Participants
Behrang Amini, MD, PhD, Houston, TX (*Presenter*) Nothing to Disclose
Robert D. Boutin, MD, Davis, CA (*Abstract Co-Author*) Nothing to Disclose
Leon Lenchik, MD, Winston-Salem, NC (*Abstract Co-Author*) Nothing to Disclose
Sean P. Boyle, Sacramento, CA (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

Bamini@mdanderson.org

PURPOSE

Computed tomography (CT) is being increasingly used for the assessment of sarcopenia, often by non-radiologists who may not be aware of the impact of technical parameters on muscle metrics. We sought to perform a systematic review of all relevant studies that used CT muscle measurements to assess sarcopenia to identify the differences between technical parameters used.

METHOD AND MATERIALS

A comprehensive search of PubMed from 1983-2017 was performed to identify studies that used CT measurements of muscle to assess for sarcopenia. Review articles were excluded. The following technical parameters used to measure muscle metrics were compared: slice thickness, kVp, mAs, helical pitch, reconstruction method, and use of intravenous (IV) contrast.

RESULTS

From the 654 articles identified, 388 studies met the inclusion criteria for the systematic review. Slice thickness was not reported in 63% of studies. When reported, the most commonly used slice thickness was 10 mm (14%). kVp was not reported in 73% of studies. When reported, the most common kVp was 120 (19%). mAs was not reported in 75% of studies. When reported, the most common mAs values were between 200 and 300 (7%). Helical pitch and reconstruction algorithm were not reported in 98% of studies and IV contrast use was not reported in 94% of studies.

CONCLUSION

There is a significant deficiency in reporting of CT technical parameters used for measuring muscle indices which may affect the generalizability of results in the sarcopenia literature.

CLINICAL RELEVANCE/APPLICATION

Comparison between publications in the sarcopenia field is hampered by deficiency in reporting of CT technical parameters.

SSC10-06 Inter- and Intraobserver Variability of an Anatomical Landmark-Based, Manual Segmentation Method by MRI for the Assessment of Skeletal Muscle Fat Content and Area in Subjects from the General Population

lena.kiefer@med.uni-tuebingen.de

PURPOSE

Changes in skeletal muscle composition, such as fat content and mass, may exert unique metabolic and musculoskeletal risks; however, the reproducibility of their assessment is unknown. We determined the variability of the assessment of skeletal muscle fat content and area by magnetic resonance imaging (MRI) in a population-based sample.

METHOD AND MATERIALS

A random sample from a prospective, community-based cohort study (KORA-FF4) was included. Skeletal muscle fat content was quantified as proton-density fat-fraction (PDFF) and area as cross-sectional area (CSA) in multi-echo Dixon sequences (TR 8.90ms, six echo times, flip-angle 4°) by a standardized, anatomical landmark-based, manual skeletal muscle segmentation at level L3 vertebra by two independent observers. Reproducibility was assessed by intra-class correlation coefficients (ICC), scatter and Bland-Altman plots.

RESULTS

In 50 included subjects (mean age 56.1±8.8years, 60.0% males, mean BMI 28.3±5.2) 2'400 measurements were obtained. Inter-observer agreement was excellent for all muscle compartments (PDFF: ICC0.99, CSA: ICC0.98) with only minor absolute and relative differences (-0.2±0.5%, 31±44.7mm2; -2.6±6.4% and 2.7±3.9%, respectively). Intra-observer reproducibility was similarly excellent (PDFF: ICC1.0, 0.0±0.4%, 0.4%; CSA: ICC1.0, 5.5±25.3mm2, 0.5%, absolute and relative differences, respectively). All agreement was independent of age, gender, BMI, body height and visceral adipose tissue (ICC0.96-1.0). Furthermore, PDFF-reproducibility was independent of CSA (ICC0.93-0.99).

CONCLUSION

Quantification of skeletal muscle fat content and area by MRI using an anatomical landmark-based, manual skeletal muscle segmentation is highly reproducible.

CLINICAL RELEVANCE/APPLICATION

An anatomical landmark-based, manual skeletal muscle segmentation provides high reproducibility of skeletal muscle fat content and area and may therefore serve as a robust proxy for myosteatosis and sarcopenia in large cohort studies.

SSC10-07 Cortical Bone Porosity Assessment in Human Tibial and Fibular Cortex Using Ultrashort Echo Time Magnetization Transfer (UTE-MT) MRI

sjerban@ucsd.edu

PURPOSE

To investigate the relationship between macromolecular fraction (MMF), obtained from UTE-MT modeling, and bone porosity, as measured using high-resolution micro-computed tomography (µCT).

METHOD AND MATERIALS

Eighteen cortical bone specimens were harvested from human tibial and fibular midshafts (63±19 and 52±18 years old). Specimens were scanned using an 8-channel knee coil on a 3T clinical scanner (MR750, GE). The UTE-MRI scans involved: A) an actual flip angle-variable TR (AFI-VTR) method, (AFI: TE=0.032, TR=20,100 ms, FA=45°; VTR: TE=0.032, TR=20 to 100 ms, FA=45°) for T1 measurement, which is a prerequisite for accurate MT modeling, and B) a 3D UTE-Cones-MT sequence (saturation pulse power=500,1000,1500°, frequency offset=2 to 50 kHz, FA=7°) for MT modelling. Field of view (FOV), matrix dimension, nominal in-plane pixel size, and slice thickness were 14 cm, 256×256, 0.54 mm, and 2 mm, respectively. Afterward, specimens were scanned using a Skyscan 1076 (Kontich, Belgium) µCT at 9 µm3 voxel size. Pearson's correlations were calculated between UTE-MT results and µCT-based measures (porosity and bone mineral density, BMD) using the data in 12 and 4 ROIs in each tibial and fibular sample, respectively. ROIs were selected at different cortical bone bands to provide an adequate range of porosity.

RESULTS

Figures 1a-f show MMF, porosity, and BMD pixel maps for a representative tibial and fibular specimen, respectively. Regions of higher MMF corresponded to the regions of lower porosity in the porosity maps. Figures 1g-j demonstrate the correlations between MMF and µCT measures for tibial and fibular bone specimens, respectively. MMF presented very good correlations with µCT measures.

CONCLUSION

MMF obtained from MT modeling, as a measure for collagen content, showed very good correlations with µCT measures regardless of the fibular of tibial harvesting sites. This study highlighted UTE-MT MRI techniques as a useful method to assess bone porosity, which may be used in future clinical studies.

CLINICAL RELEVANCE/APPLICATION

A UTE-MRI-based technique, to estimate the collagen backbone content which correlates greatly with the bone porosity may help diagnose bone diseases earlier and more accurately.

SSC10-08 Diagnostic Performance of Phantomless Dual-Energy CT for Volumetric Bone Mineral Density Assessment in Comparison to CT Hounsfield Unit Measurements Using Dual X-Ray Absorptiometry as Standard of Reference

boozchristian@gmail.com

PURPOSE

To evaluate the diagnostic performance of a phantomless dual-energy computed tomography (DECT) postprocessing algorithm for volumetric bone mineral density (BMD) assessment of the lumbar spine compared to Hounsfield unit (HU) measurements.

METHOD AND MATERIALS

We retrospectively analyzed 200 lumbar vertebrae in 53 patients who had undergone third-generation dual-source DECT and dual x-ray absorptiometry (DXA) examinations of the lumbar spine within 7 days between March and December 2017. For volumetric BMD assessment, dedicated phantomless DECT postprocessing software which allows for freely rotatable color-coded three-dimensional visualization of trabecular BMD distribution using three-material decomposition was applied. In addition, HU measurements were performed on standard bone reconstructions by defining five trabecular regions of interest (ROI) per vertebra. Results of both approaches were compared regarding the diagnostic accuracy using the DXA T-score according to the World Health Organization as standard of reference for detecting osteoporosis.

RESULTS

DXA revealed a total of 92 osteoporotic lumbar vertebrae. A BMD cut-off of 92 mg/cm³ at phantomless DECT yielded 98.9% sensitivity and 91.6% specificity for detecting osteoporosis; 93.3% of vertebrae below this threshold were diagnosed with osteopenia/osteoporosis according to DXA and 80.2% above showed normal BMD at DXA. A trabecular ROI attenuation cut-off of 157 HU showed 71.0% sensitivity and 66.4% specificity for osteoporosis; 73.3% of vertebrae below this threshold were diagnosed with osteopenia/osteoporosis according to DXA and 41.0% above showed normal BMD at DXA. Area under the curve for detecting osteoporosis was 0.953 for phantomless DECT and 0.754 for HU-based analysis (p<0.001). Pearson product-moment correlation showed higher correlation between BMD results of phantomless DECT and DXA (r=0.848) compared to HU and DXA values (r=0.438) (p<0.001).

CONCLUSION

A phantomless DECT postprocessing algorithm for volumetric BMD assessment of the lumbar spine is significantly superior compared to HU measurements regarding the diagnostic accuracy for detecting osteoporosis.

CLINICAL RELEVANCE/APPLICATION

Opportunistic screening for osteoporosis using HU measurements on CT images as previously suggested in recent literature is less accurate than a phantomless color-coded DECT postprocessing algorithm which can be applied to routine DECT without requiring protocol changes.

SSC10-09 Effects of Nutrition, Exercise, and Medication on Bone Microarchitecture Assessed by HR-pQCT Measurements in Long-Term HIV-Infected Individuals

Monday, Nov. 26 11:50AM - 12:00PM Room: S102CD

PURPOSE

In long-term HIV-infected individuals, low bone density and increased fracture risk have emerged as significant comorbidities. Our aim was to assess the influence of exercise, nutrition, and medications on bone microarchitecture using high-resolution peripheral quantitative CT (HR-pQCT) in long-term HIV-infected individuals.

METHOD AND MATERIALS

Twenty-nine HIV-infected subjects (3 postmenopausal women, 26 men) were prospectively enrolled in our study (BMI 26.1±4.3 kg/m2, age 56.9±5.6, years diagnosed with HIV 20.7±8.8). Questionnaires included the revised Community Healthy Activities Model Program for Seniors (CHAMPS), the Mini Nutritional Assessment (MNA) as well as medication assessments. Participants underwent radius and tibia HR;pQCT and laboratory evaluation. Multivariable linear regression models were used to evaluate the effects of exercise, nutritional status, tenofovir disoproxil fumarate (TDF) and protease inhibitor (PI) use on bone microarchitecture, adjusting for all demographic risk factors.

CONCLUSION

Cortical bone in HIV-infected individuals is detrimentally affected by malnutrition, while trabecular bone is detrimentally affected by previous use of TDF in combination with a PI. In long-term HIV-infected subjects, nutritional support could potentially be more relevant for bone health compared to physical activity.

CLINICAL RELEVANCE/APPLICATION

Long-term HIV-infected individuals could particularly benefit from nutritional assessment and intervention as well as avoiding use of TDF with PIs to prevent compromised bone health.

PURPOSE

Blunt cerebrovascular injury (BCVI) occurs in 0.2-2.7% of blunt trauma patients, and is the cause of stroke in approximately ~2% of all patients and 10-25% of young patients. BCVI patients are at highest risk of stroke within 10-72 hours following injury, with the likelihood of stroke increasing with dissection grade. The Denver screening criteria are the most commonly implemented criteria for screening BCVI.The study aims to quantify the variance of current practice at our institution from the established Denver criteria.

METHOD AND MATERIALS

A retrospective chart review was conducted on consecutive blunt trauma patients admitted to our institution from Jan 1, 2010-Dec 31, 2015. Imaging studies were reviewed by a neuroradiologist and an emergency radiologist. Patients were assessed for clinical and radiological Denver criteria, presence of dissection on CTA, medical history, treatment, and outcome.

RESULTS

3004 consecutive patients were included. 757 (25.2%) patients were Denver positive, but only 336 received a CTA, and nearly half with detectable dissections. Of the Denver positive patients, 54 (7.1%) patients had an in-hospital stroke (total 122 strokes), with 15 (26.8%) patients having a detectable stroke on their primary CT scan. 33 strokes were due to traumatic vessel injury; 43 were due to arterial compression; and 46 did not have a discernable cause, in part due to lack of CTA screening. Of the strokes due to dissection, 3 (9.1%) were Biffl Grade (Gr) 1; 6 (18.2%) Gr2; 12 (36.4%) Gr3; 10 (30.3%) Gr4; 2 patients had an injury in a vessel other than the carotid or vertebral. 7 patients had an arterial injury requiring neurological intervention, including intracranial ICA and ACA pseudoaneurysms. 156 (6.9%) of Denver negative patients underwent CTA, with 19 having detectable dissections. A total of 13 Denver negative patients had stroke, only 3 due to dissection: 2 Gr3 and 1 Gr4.

CONCLUSION

Almost 30% of Denver positive patients have a stroke earlier than the estimated 10-72 hour window, highlighting the need for early medical assessment and preventative measures. CTAs are underutilized and a considerable amount of patients have stroke as a result of lower-grade (1-2) dissections.

CLINICAL RELEVANCE/APPLICATION

Early screening for arterial injury and early insitiution of antiplatelet or interventional therapy, depending on the degree of vessel injury, may help to prevent post traumatic strokes.

SSC11-02 Brain Extraction in Susceptibility-Weighted MR Images Using Deep Learning

Monday, Nov. 26 10:40AM - 10:50AM Room: S402AB

For information about this presentation, contact:

kevin.koschmieder@radboudumc.nl

PURPOSE

Brain extraction methods in MRI have so far been exclusively developed for T1- and T2-weighted images. A deep neural network is presented to segment the brain tissue in susceptibility-weighted images (SWI) in healthy individuals and patients with traumatic brain injury (TBI).

METHOD AND MATERIALS

In total, MRI scans from 33 patients with moderate to severe TBI and 18 healthy controls were collected. SWIs were acquired with 27ms TR, 20ms TE, 15° flip angle, and 0.98x0.98x1.00mm³ voxel size on a 3T Siemens MRI scanner. A small scale 2D-U-Net was implemented (18 convolution layers, max. 256 features per layer) processing a volume in axial direction. The U-Net architecture allowed the model to utilize both local and contextual information. The output probability maps were thresholded and possible outliers were removed by taking the largest connected component. 20 TBI patients and 10 controls served as a test set, the remaining patients were used for training. The reference standard were brain masks obtained with SPM, a publicly available software package commonly used for brain extractions in MR neuroimaging, but not optimized for SWI sequences. These annotations were visually inspected. The results of the deep learning method were visually inspected for completeness and overall quality. Dice similarity coefficient (DCS) and the modified Hausdorff (MHD) distance were reported for the test set.

RESULTS

The DCS was 0.98±0.002 per volume at the chosen operating point on the SPM standard and the MHD was 0.93±0.11mm per volume. It took less than 10 seconds to compute the complete 3D brain mask on a modern GPU. Overall, our method was capable of learning from a sub-optimal reference standard and extracting the brain from an SWI scan. It mimicked some of the deficiencies of the SPM brain masks, such as occasional failures in the most inferior or superior axial slices, but also mitigated others through generalization over the training set. Holes in the mask caused by contusions or hematomas were less prevalent with the 2D-U-Net than with SPM.

CONCLUSION

The 2D-U-Net method provides fast brain extractions in MR-SWI.

CLINICAL RELEVANCE/APPLICATION

SWI is the best modality to establish the extent of cerebral microbleeds in TBI. Brain extraction in SWI is the first step in the development of computer-aided systems detecting these microbleeds.

SSC11-03 Subconcussive Head Impacts May Alter Metrics Associated with Normal Pruning in Youth and High School Football Players

PURPOSE

To determine whether exposure to repetitive subconcussive impacts affects fMRI metrics associated with normal pruning in youth and high school football players over a single season.

METHOD AND MATERIALS

Youth and high school football players are exposed to high numbers of head impacts over the course of a season [1]. The spectral power of resting state networks typically decreases as a function of age and has been interpreted as a sign of normal Gray Matter (GM) pruning [2]. We hypothesized that a season of contact sports will alter this relationship. Specifically, there will be an increase in power of the DMN and consequent change in GM volume (GMV) associated with normal pruning.Sixty age matched players without history of developmental, neurological, or psychiatric abnormalities and no history of concussion during or prior to the season were split into high impact (HI) (24) and low impact (LI) (36) groups, respectively based on each player's risk-weighted cumulative exposure (RWEcp)[3,4]. The RWEcp represents the summed risk of concussion for each impact over the season as derived by the Head Impact Telemetry System (HITS) data [1]. High order ICA (n=60) was performed to extract independent components using the GIFT toolbox [5]. Subject specific time courses for each subject were converted into a power spectrum through power spectral decomposition. Five components of the DMN were identified and changes in the power of the network were computed as post-season minus pre-season values (ΔPSD). Following bonferroni correction, only the anterior cingulate network

demonstrated a significant difference in ΔPSD and was used as a mask to determine GMV using VBM8. A two-sample t-test was performed to determine significant changes in ΔPSD and ΔGMV between the groups.

RESULTS

The frontal DMN (FDMN) demonstrated a significant increase in power in the HI group (p-value: 0.00018). A significant increase in GM volume was found in the same frontal regions of the DMN (p-value: 0.005) (Fig.1) for HI group.

CONCLUSION

Our results suggests that normal GM pruning is affected in the HI group, over a single season of contact sport. Longitudinal studies are needed to understand the long-term changes in resting state networks and effects on functional brain health.

CLINICAL RELEVANCE/APPLICATION

This work demonstrates that playing a season of contact sports may affect normal GM pruning in high school and youth football players

SSC11-04 Source Space MEG Delta Waves Increase Following Concussion

Monday, Nov. 26 11:00AM - 11:10AM Room: S402AB

elizabeth.davenport@utsouthwestern.edu

PURPOSE

The purpose of this study is to determine if delta waves, measured by magnetoencephalography (MEG), increase due to a sports concussion.

METHOD AND MATERIALS

From a larger study on subconcussive impacts in high school football, five players were diagnosed with a concussion during the season (mean age=16.1). Subjects followed returned-to-play protocols. Eight minutes of eyes-open, resting-state MEG data were acquired for each subject and control using a 275 channel CTF whole-head system. Football players were scanned pre-season, within 36 hours post-concussion, and post-season. Seven age and gender matched non-contact sports athletes (controls) were also recruited (mean age=16.2). Controls received baseline and follow-up scans 4 months later. Using Brainstorm, MEG data were baseline corrected, band-stop filtered (60Hz), down-sampled to 250Hz, and band-pass filtered to 1-100Hz. Eye blinks, and muscle artifacts were removed using independent component analysis. Data was source localized using a minimum norm method. The average whole-brain power of the delta frequency and total power was computed for each scan. The delta frequency power was normalized by the total power. In the concussed football players, pre-season delta power was subtracted from post-concussion delta power. For the control subjects, baseline delta power was subtracted from the 4-month follow-up scan. A t-test was performed to compare the change in delta power of controls to the change in delta power of concussed football players.

RESULTS

The change in delta power following concussion was significantly different from controls (p=0.014). In addition to the statistical difference, delta waves visibly increased from pre-season to post-concussion (Figure 1).

CONCLUSION

We demonstrate that a single concussion can visibly and statistically increase delta frequency power in MEG.

CLINICAL RELEVANCE/APPLICATION

Traditional imaging is typically unremarkable in concussion. This study demonstrates that MEG may be a new and useful diagnostic tool for concussion.

SSC11-06 Longitudinal Hippocampal Subfield Volume Changes in Collegiate Football Athletes

PURPOSE

Collegiate football athletes are subject to repeated head impacts. The hippocampus, a structure crucial for memory, is of particular interest in the study of football. There is a lack of prospective, longitudinal data on the hippocampus in football.

METHOD AND MATERIALS

A prospective cohort study was conducted over a 4-year period composed of 63 football and 34 volleyball male collegiate athletes. Automated segmentation provided hippocampal subfield volumes from whole brain axial T1 images and high-resolution coronal-oblique T2 images. At baseline, these volumes were linearly regressed to compare football with volleyball. For the longitudinal data, a linear mixed-effects model assessed the interaction between sport and time.

RESULTS

Comparing sports at baseline, the football athlete group showed a smaller subiculum volume (coefficient=-67.77, 95% CI [-120.20, -15.33], P=.012). The longitudinal interaction between sport and time demonstrated a significant decrease in total hippocampal volume in athletes who play football relative to volleyball (coefficient=-90.27, 95%CI [-177.05, -3.48], P=.041), most significantly within the CA1 hippocampal subfield (coefficient=-28.55, 95%CI [-50.94, -6.17], P=.012). This interaction within CA1 was significant even when in-study concussions were excluded (coefficient=-34.22, 95%CI [-60.79, -7.65], P=.012). Within the right CA1, this volume decrement was observed in football even in isolation from volleyball (coefficient=-22.96, 95%CI [-40.13,-5.80], P=.009).

CONCLUSION

A prospective longitudinal evaluation comparing football and volleyball athletes showed a decrease in hippocampal volumes over time in football athletes. This longitudinal divergence was most significant in CA1, in contradistinction to baseline differences that were most significant in the downstream subiculum.

CLINICAL RELEVANCE/APPLICATION

Given these observed hippocampal volume alterations, further research must be done to assess the potential relevance to cognitive function.

wangzhuonan424@stu.xjtu.edu.cn

PURPOSE

To examine dynamic inter-hemispheric functional connectivity in mild traumatic brain injury (mTBI) patients with longitudinal observations and how machine learning can be used alongside voxel mirrored homotopic connectivity (VMHC) to accurately separate mTBI patients from healthy controls and predict the future long-term development of clinical significant cognitive impairment following mTBI.

METHOD AND MATERIALS

Sixty-one patients with mTBI and forty-four age- and gender-matched subjects underwent clinical and neuropsychological evaluations with fMRI scanning. All of patients was initially evaluated within 14 days post-injury and follow-up at 6-12 months.We adopted VMHC to quantifies the functional connectivity between bilateral homotopic voxels. Next, the multivariate analysis of VMHC results was performed with linear support vector machines (SVM). The commonly affected functional brain regions were selected as the feature metrics combined with SVM to predict clinical outcome in individual patients.

RESULTS

Compared with healthy controls, mTBI patients showed decreased VMHC in the dorsal lateral prefrontal cortex and supplementary motor area and increased VMHC in the ventrolateral prefrontal cortex, orbitofrontal cortex and posterior cingulate cortex(P <0.005) in sub-acute phase. In 6-12 months, decreased regions were completely disappeared while original increased regions showed continuously and extend patterns. The SVM classifier based on the sub-acute phase VMHC results yielded an accuracy rate of 82% (with a sensitivity of 88.1% and specificity of 92.9%) after 1000 permutation, which was significantly better than chance (P<0.005). Combined the sub-acute phase VMHC results with support vector regression machines, we found significant positive correlations between actual neuropsychological values and predicted values in three clinical tests (PSS, R2 = 0.83; HAMD, R2 =0.87; FSS, R2 =0.91).

CONCLUSION

The VMHC results successfully revealed the time correlated functional connectivity alteration in some particular brain regions and their association with clinical outcomes. We further provided evidence that using VMHC with machine learning approache has the potential to augment diagnosis in individual patients following mTBI.

CLINICAL RELEVANCE/APPLICATION

We demonstrate relationships between inter-hemispheric functional connectivity abnormalities and predictions about individual patients' clinical outcomes.

SSC11-09 Is a Follow-Up CT After 4 Hours Necessary for Falx and Tentorial SDH?

oztekma@uw.edu

PURPOSE

The mandatory 4 hour follow-up CT (4Hr-CT) has been the standard for patients with traumatic intracranial hemorrhage, including Subdural Hematoma (SDH) in the Tentorium (T-SDH) and Falx (F-SDH). The purpose of this study was to assess the effectiveness of 4Hr-CT for isolated F-SDH and T-SDH in the management of traumatic intracranial hemorrhage.

METHOD AND MATERIALS

182 consecutive cases with acute SDH treated at a major trauma center between December 2015 and March 2018 were retrospectively reviewed. Isolated F-SDH and/or T-SDH were identified in 54 patients (30%). All patients had initial and 4-HrCT. The size of the SDH was measured parallel or perpendicular to the falx or tentorium (long and short axis, respectively). The morphology of the SDH, mass effect, extent of involvement and interval change at 4-HrCT were evaluated.

RESULTS

All the F-SDH and T-SDH had a pancake-like configuration with the long-axis (median 38 mm) greater than the short axis (median 3 mm) by 10 fold on average (p<0.001). An interval increase along the short axis was seen in only 5 F-SDH (16%) and 7 T-SDH (19%), with a maximum change of 2 mm. Interval increases were more prominent along the long axis: 18 F-SDH (56%) and 19 T-SDH (51%), with a maximum change of 118 mm and 21 mm, respectively. F-SDH and T-SDH were contiguous in 14 out of the 18 patients with both hematomas. No patients had worsening focal neurological findings after initial diagnosis required surgical intervention or died during their hospital stay (rate 0%, 95% CI 0-6.6%).

CONCLUSION

Based upon our limited data, the current standard protocol of a mandatory 4-hour follow-up CT is not cost-effective in the management of patients with isolated F-SDH and/or T-SDH. These SDHs expand minimally along the short axis, if at all, without causing significant mass effect. The high incidence of continuity between co-existing F-SDH and T-SDH, characteristic anatomic structure, and deformability of the tentorium and falx may serve as a natural barrier limiting the overall growth of SDH, while providing potential space for decompression by longitudinal spread of the SDH.

CLINICAL RELEVANCE/APPLICATION

The current standard protocol of a mandatory 4-hour follow-up CT for acute intracranial hemorrhage is not needed for patients with isolated Falx and/or Tentorium Subdural Hematoma.

PURPOSE

Our objective was to estimate the impact of respiratory training in improving image quality of images obtained from T1 Star VIBE magnetic resonance imaging (MRI).

METHOD AND MATERIALS

This prospective study was approved by the local ethics committee. Totally of 6 volunteers were in the study. The volunteers underwent 3 Tesla MR scanner (Siemens-Skyra) using T1 Star VIBE for two times within 24-48h. The MRI protocol (MAGNETOM 3.0T SKYRA MR scanner, Siemens healthcare, Erlangen, Germany) included a Prototyped T1-weighted 3D Star VIBE sequence(TE/TR:1.39/2.79,slice thickness 1.2mm)and T2 blade. The volunteers accepted MRI examination directly at the first scan, while they receive respiratory training before the MRI examination to make them keeping calm and breathing evenly. The observation of lung markings were used to evaluate image quality of each examination. The display of lung markings were observed in three zone (upper, middle and bottom according to the T4 and T8 vertebra level) by two experienced radiologists independently. And a 3-point system were used (3-point: no artifacts, noise, or with a little artifacts, less noise, the image quality is better; 2-point: more artifacts, more noise, image quality is acceptable; 1-point: obvious artifacts, large noise, image quality is poor.) The image quality of T1 Star VIBE MRI in two scans were compared.

RESULTS

All the volunteers finished MRI examination. The image quality scores of three zones(upper, middle and bottom)in first scans were 2.5±0.55,2.17±0.75,1.5±0.55, and those were 2.83±0.41,2.67±0.52,2.33±0.82 in the second scans. The image quality scores of the lower part of the lungs had significant difference among the two groups(t=2.71,p=0.042).

CONCLUSION

Respiratory training could improve the image quality,especially at the bottom of the lung and increase the lesion detection rate and accuracy of diagnosis.

CLINICAL RELEVANCE/APPLICATION

Respiratory training may be used to improve the image quality of images obtained from T1 Star VIBE magnetic resonance imaging.

SSC12-02 MRI Safety: Digital Measurement of Magnetically Induced Torque Based on ASTM F2213

Monday, Nov. 26 10:40AM - 10:50AM Room: N226

CONCLUSION

Ferromagnetic stainless steel screws may exhibit large magnetically induced torque within the homogeneous magnetic field during MRI examination. For analysing of these magnetically induced torque a digital measuring device could be developed, which allows to simplify and accelerated the standard test method ASTM F2213.

Background

Performing MRI examinations in patients who use implantable medical devices involve safety risks both for the patient and the implant. The aim was a digital measuring device for measuring magnetically induced torque on medical implants in magnetic field center of 1.5T and 3T MR scanner.

Evaluation

An MR-safe measuring platform was developed according to the standard ASTM F2213 and combined with a precision balance (PCB 1600-2, Kern & Shon GmbH, Germany). The evaluation was performed with stainless steel screws (length 24, 47 and 71 mm) and a neurostimulator (LibraXP, St. Jude Medical, USA) in the magnetic field center of a 1.5T and 3T MRI (Magnetom Avanto and Magnetom Prisma, Siemens, Germany). The torque was measured at 10-degree increments as the implant was rotated relative to the static magnetic field for all possible orientations of the object.

Discussion

The measured force depends on the object orientation within the static magnetic field. The neurostimulator had a torque of 1 +- 1 N*mm (maximum 3 N*mm) for a rotation about the vertical axis, 39 +- 20 Nmm (maximum 64 N*mm) for rotation about the longitudinal axis and 40 +- 20 N * mm (maximum 64 N*mm)) for a rotation about the transverse axis. This corresponds to a maximum acting force of 1.28 N (mass 0.131 kg). The magnetostatic torque is proportional to the length of the test object. For the stainless steel screws, the torque is 66 +- 37 N*mm (maximum 108 N*mm) for a length of 24 mm, 139 +- 86 Nmm (maximum 247 N*mm) for a length of 47 mm and 252 +- 145 Nmm (maximum 434 N*mm) for a length of 71 mm.

SSC12-03 Numerical Simulation of Thermal Risk Assessment for a Compact MR Scanner

PURPOSE

Brain imaging on conventional MRI scanners commonly relies on a whole-body (WB) radiofrequency (RF) transmit coil to provide a uniform excitation (B1+) field. As such, patient RF power deposition may be an issue during high RF duty-cycle scanning. A recently developed compact 3T (C3T) MRI scanner with high performance gradients [1,2] has a dedicated RF transmit coil that exposes only the head region. For neuroimaging, the C3T scanner may provide lower RF power deposition compared to conventional WB scanners, thus enabling the development of advanced neuroimaging techniques.

METHOD AND MATERIALS

A 16-rung high-pass birdcage head coil (127.74 MHz, 37-cm ID, driven in quadrature) was modelled using full-wave electromagnetic FDTD simulation software, Sim4Life (ZMT, Zurich, Switzerland). Simulations were performed to predict specific absorption rate (SAR) distributions using the Duke human body model as a test phantom at a landmark location of the glabella. A large-diameter standard 3T 16-rung WB birdcage coil was also modeled for comparison. Input power on the larger coil was scaled to reach the same average B1+ for the glabella slice as in the C3T, and scaled SAR maps were used as inputs to a time-dependent Penne's bioheat equation [3] thermal solver. All thermal simulations were run using 200W continuous input power for 60 minutes, with the proper scaling for the WB coil according to B1+. All material properties were set to nominal literature values [4].

RESULTS

The following were observed as a result of the simulations of the C3T compared to whole-body MRI: (i) ~20% reduced average SAR in the head and neck region, (ii) lower (5.5°C vs 6.5°C) peak temperature rise in the brain regions, and (iii) minimal (~0°C) temperature rise in the neck region was observed in the C3T scanner compared to the ~7°C rise in the WB MRI, due to reduced body mass exposure in the dedicated scanner.

CONCLUSION

The C3T provides a reduction of ~20% in thermal risk over a conventional whole-body MRI due to the much smaller exposed body mass to achieve the same B1+ excitation field in the brain. This allows for improved performance from the SAR demanding applications. 1.FooT,MRM,2018 2.WeaversP,MPhys,2016 3.Pennes.JAPhys1948 4.GabrielS,PMB1996

CLINICAL RELEVANCE/APPLICATION

Advanced neuroimaging techniques require faster imaging thus creating potential for increased patient heating. Here we investigate the thermal risk of a recently developed head-only MRI scanner.

SSC12-04 Improving Resolution, Distortion, and SNR of Clinical Diffusion Weighted Images Using Deep Learning

Monday, Nov. 26 11:00AM - 11:10AM Room: N226

Participants
Junshen Xu, Beijing, China (*Presenter*) Nothing to Disclose
Nan Liu, Shanghai, China (*Abstract Co-Author*) Employee, Shanghai United Imaging Healthcare Co, Ltd
Xiaodong Ma, Beijing, China (*Abstract Co-Author*) Nothing to Disclose
Jun Xie, Shanghai, China (*Abstract Co-Author*) Employee, Shanghai United Imaging Healthcare Co, Ltd
Guobin Li, Shanghai, China (*Abstract Co-Author*) Employee, Shanghai United Imaging Healthcare Co, Ltd

Nan-Jie Gong, Houston, TX (*Abstract Co-Author*) Employee, UIH America, Inc
Kui Ying, PhD, Beijing, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Diffusion weighted images (DWI) are commonly acquired with single-shot Echo-planar imaging (EPI) sequence, which is suffered from image distortion due to eddy current and B0 field inhomogeneity as well as low resolution especially in clinical settings. Multi-shot DWI has been demonstrated to outperform single-shot DWI in these aspects with optimized SNR. However, multi-shot DWI has not been widely adopted clinically due to long scan time.

METHOD AND MATERIALS

We proposed a method of generating high-quality DWI from its low-quality counterpart using fully convolutional neural network. Brain DWI data were acquired with a 3T MR system (uMR 780) using both single-shot (128*128) and four-shots (160*160) EPI sequences. The multi-shot EPI DWI, which has higher resolution and less distortion, served as ground truth in training process. Our dataset contains 38 pairs of single-shot and multi-shot DWI. Each pair of images were resized to 320x320 and then cropped randomly to generate 50 patches (128x128). To make full use of available data and reduce the bias, we adopted a 10-fold cross validation in experiments.

RESULTS

For quantitative evaluation, we calculated peak signal-to-noise ratio (PSNR) and structural similarity index (SSIM). Results showed that the proposed method gain 4.2dB in PSNR and 0.22 in SSIM compared with single-shot DWI. Additionally, perceptual results showed that our neural network can recover details and reduce distortion in single-shot DWI.

CONCLUSION

Results imply that we can improve resolution, SNR and reduce distortion of single-shot EPI-DWI using deep neural network, which potentially enables acquiring high quality DWI without lengthening scan time.

CLINICAL RELEVANCE/APPLICATION

This method could improve resolution, SNR and reduce distortion of clinical DW images without lengthening scan time.

SSC12-05 Fast Field-Cycling MRI Technology: Prototype Human Scanner and First Clinical Results

Monday, Nov. 26 11:10AM - 11:20AM Room: N226

d.lurie@abdn.ac.uk

PURPOSE

A prototype human-scale Fast Field-Cycling (FFC) MRI scanner has been built, allowing good quality images at ultra-low field (0.2 mT) with enhanced T1-contrast. It has been used to image the brain in patients with acute ischemic stroke.

METHOD AND MATERIALS

FFC-MRI is a new method, designed to image at ultra-low field while preserving signal-to-noise ratio (SNR) and image quality. The main field (B0) is switched between values during the pulse sequence, with polarization at the scanner's highest field, evolution (relaxation) at low field, followed by gradients, RF pulses and signal detection at high field. Our in-house-built prototype scanner has a water-cooled resistive magnet (Tesla Engineering, UK; bore 0.5 m, length 2 m) providing a maximum field of 0.2 T, with the evolution field controllable between 0.2 mT and 0.2 T; switching time between fields is 20 ms. A home-built head birdcage coil (8.5 MHz) was used. Scanner control is via a commercial console (MR Solutions, UK), running pulse sequences which include control of B0. Magnet current (up to 1950 A) is from a low-noise power supply amplifier (International Electric Company, Finland). Following research ethics committee approval, patients (N=10) with acute ischemic stroke were recruited and gave informed consent. They were scanned by FFC-MRI within 24-96 h after presentation. Duration of the FFC-MRI examination was typically 45 minutes, including setup, scout and FFC images at five evolution fields (0.2 mT to 200 mT). Patients were scanned by CT prior to FFC-MRI and some had 3 T MRI (N=2) including DWI.

RESULTS

The usable range of B0 during the evolution period was validated in phantoms. In scans of patients with acute ischemic stroke, T1-

weighted FFC-MRI images exhibited hyper-intense regions, with contrast increasing markedly as the evolution magnetic strength field decreased, with maximum lesion intensity at the lowest field used (0.2 mT). The infarct region seen by FFC-MRI correlated well with the appearance in CT and DWI (where appropriate) images.

CONCLUSION

A whole-body FFC-MRI scanner was built and has been used to image the brain in patients with ischemic stroke, in the first-ever clinical demonstration of this technology.

CLINICAL RELEVANCE/APPLICATION

FFC-MRI is a new modality which can generate diagnostic-quality images at ultra-low magnetic fields (e.g. 0.2 mT), with significantly-enhanced endogenous T1-contrast compared to conventional MRI.

SSC12-06 Joint Cardiovascular Magnetic Resonance Image Reconstruction and Segmentation Using Deep Learning Image-to-Image Translation

Monday, Nov. 26 11:20AM - 11:30AM Room: N226

Participants
James W. Goldfarb, PhD, Roslyn, NY (*Presenter*) Nothing to Disclose
Jie J. Cao, MD, Roslyn, NY (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To develop and test a joint image reconstruction and semantic segmentation method for functional right and left ventricular cardiovascular MR imaging.

METHOD AND MATERIALS

Image-to-image translation using a generative adversarial network (GAN) was implemented using PyTorch v 0.3.0, translating source radial CMR sinograms (r-theta space) to semantic segmentation of the left and right ventricles. 1700 short axis cardiac MR images were used for training (n=1400), simulation and validation(n=300). Each had expert manual segmentation of the LV and RV bloodpools. Deep learning via a U-net convolutional neural network was used for image-to-image translation (so-called 'pix2pix'), providing semantic segmentation masks of the RV and LV directly from raw CMR k-space data. The U-net Generator was trained with an adversarial loss for 100 epochs. Reconstruction/segmentation of the RV and LV was studied with undersampling factors of up to 8. The Sørensen-Dice similarity index was used to compare RV and LV masks to manual segmentation in validation data, undersampled simulations, and prospectively collected CMR radial exams (n=15).

RESULTS

The GAN trained quickly, providing excellent segmentation of both the LV and RV with LV Dice index= 0.989±0.003 (range: 0.975-0.996) and RV Dice Index = 0.986±0.005 (range: 0.938-0.995). Deep learning provided segmentation consistent with clinical standards, where trabeculae and papillary muscles are included inside of ventricular bloodpool segmentations. With an acceleration factor of 8, quality segmentations were maintained with slightly reduced Dice Indices: LV Dice index= 0.961±0.016 (range: 0.872 - 0.993); RV Dice index= 0.937±0.023 (range: 0.734-0.981). In-vivo prospective reconstructions using complex radial CMR data yielded similar Dice Indices.

CONCLUSION

Image-to-image translation is a viable method for radial MR image reconstruction and provides a framework for image reconstruction, acceleration and segmentation. In this proof-of-concept study, simulations confirmed the feasibility of quantitative LV and RV imaging with image-to-image translation and prospective in vivo radial imaging yielded encouraging results with acceleration factors of up to 8.

CLINICAL RELEVANCE/APPLICATION

A deep learning approach is presented which 'translates' CMR data directly to quantitative LV and RV segmentation and eliminates the need for conventional backprojection and gridding along with manual segmentation.

SSC12-07 Optimization of Pulse Sequence Ordering for Automated Fat and Iron Quantification

Monday, Nov. 26 11:30AM - 11:40AM Room: N226

Participants
Daniel J. Margolis, MD, Los Angeles, CA (*Presenter*) Consultant, Blue Earth Diagnostics Ltd
Alexander Gavlin, MD, Bronx, NY (*Abstract Co-Author*) Nothing to Disclose
Andrea S. Kierans, MD, New York, NY (*Abstract Co-Author*) Nothing to Disclose

djm9016@med.cornell.edu

PURPOSE

Commercially available pulse sequences with dedicated post-processing software can automate the creation of maps for fat and iron quantification and make them readily available on picture archiving and communication systems (PACS) workstations, obviating the need for dedicated post-processing to be performed by the radiologist. These most commonly use a gradient multi-echo Dixon technique for derivation of fat percent (or per mille, "per thousand") and R2*, from which iron deposition can be extrapolated. However, as patients at risk for fat or iron accumulation generally also have diffuse liver disease, these scans are often combined with contrast-enhanced imaging using a hepatobiliary agent (e.g., gadoxetate disodium) with a 20-minute delayed scan in the hepatobiliary phase for improved lesion detection. This results in "down time" between the equilibration phase, generally before 5 minutes after contrast administration, and the hepatobiliary phase. It is attractive to perform as many pulse sequences as possible during this "down time," but only if they are not adversely affected by the accumulation of the contrast agent and concomitant T1- and T2-shortening. Although acquisition of the fat- and iron-quantification could be acquired after contrast administration, the degree to which contrast accumulation affects signal for these acquisitions is unknown.

RESULTS

Twelve subjects were identified. Two were excluded as outliers (one for severe steatosis, one for iron overload). Adequate measurement of FP and R2* was performed before and after contrast for the remaining 10 patients. The student's t-test showed no significant difference for FP (p=0.21) but a significant increase in measured R2* after contrast (p=0.02). The control chart shows increased variability for those R2* values acquired after contrast.

CONCLUSION

Time is the ultimate non-renewable resource. Therefore, time optimization of magnetic resonance imaging is an important consideration for optimal utilization of resources. However, this should not sacrifice diagnostic accuracy, and thereby decrease value. This investigation of fat and iron quantification shows that fat quantification appears relatively unaffected by accumulation of a T1- and T2*-shortening contrast agent, whereas R2* is unreliably increased in this setting. Fat/water quantification to measure the degree of steatosis might therefore be possible in the delayed post-contrast phase, whereas quantification of iron accumulation must be done prior to contrast administration. The control chart in this case shows the opposite of the expected effect for R2*, with an increase in variability after the intervention (contrast administration).

METHODS

The gradient multi-echo Dixon sequences were acquired before and approximately 15 minutes after administration of gadoxetate disodium (Eovist, Bayer) at 0.025 mmol/kg and 2.0 mL/sec (LiverLab q-Dixon, Siemens Healthineers, TR/TE 15.6/2.4, 4 degree flip angle, 3.5 mm slice thickness) with automated deconvolution of R2* and fat per mille (FP) maps on the scanner and sent to PACS. All sequential patients during one month were de-identified and a region of interest at least 3 cm in diameter was drawn on a motion-free image of the right lobe, with the average value recorded. The values before and after administration of gadoxetate disodium were evaluated using paired student's t-test. A "control chart" is created showing values before and after administration of contrast.

Fagan.Andrew@mayo.edu

PURPOSE

In 2017, 7T MRI entered the clinical arena with a first scanner obtaining 510(k) FDA clearance for clinical brain and knee imaging. As with previous generations of 7T (research) scanners, significant image artifacts were prevalent in the images from this system, arising from the underlying physics of the interaction of the 297 MHz radiofrequency (RF) energy with the dielectric properties of tissue and also from RF coil issues. In this paper, we present the development of techniques to mitigate these artifacts.

METHOD AND MATERIALS

Image non-uniformities arising from B1+ transmit (due to complex interference of RF waves) and B1- receive (due to RF coil receiver sensitivity problems) inhomogeneities were mitigated through the use of custom-made high permittivity dielectric pads made from a combination of CaTiO3, BaTiO3, hydroxyethyl-cellulose and D2O. Pads of differing dimensions were developed for different anatomical sites. Inter-voxel dephasing with signal drop-out due to significant magnetic susceptibility effects (e.g. at the base of the brain) was minimized through the use of localized B0 shimming techniques. DIstortions arising from long echo trains were mitigated throguh the use of high image acquisition acceleration factors facilitated by the SNR increase at 7T. Control of receiver and transmitter bandwidths were used to minimize the in- and through-plane chemical shift artifacts.

RESULTS

Tailored dielectric pads increased the SNR in areas of signal deficit by up to 27% and improved overall image uniformity. Clinical protocols were established for routine scanning in the brain (e.g. for seizure, tramautic brain injury, neurovascular diseases, fMRI-based surgical planning) and knee (e.g. meniscal tear, nerve visualization, cartilage repair); example images will be presented.

CONCLUSION

7T MRI offers significant advantages over lower-field systems, arising primarily from increased SNR and image contrast possibilities. However, the successful management of image artifacts and the development of consistent diagnostic image quality across all patient cohorts is key to its integration into a routine clinical workflow.

CLINICAL RELEVANCE/APPLICATION

This paper presents clinical protocols developed on a new generation of 7T MRI scanner, which successfully managed image artifacts and resulted in diagnostic image quality.

SSC12-09 Evaluation of Deep-Learning-Based Technology for Reducing Gadolinium Dosage in Contrast-Enhanced MRI Exams

enhaog@stanford.edu

PURPOSE

Gadolinium Deposition is one of the most urgent issues facing radiology community. In this work, we further validated a Deep Learning based contrast-boost method, on 200 patients with mixed indications, and demonstrated the generalization and robustness of the deep learning based solution to reducing gadolinium dosage while maintaining diagnostic quality.

METHOD AND MATERIALS

Dataset: A cohort of 200 patients were included in this study, with mixed indications and recieving clinically routine contrast-enhanced MRI (CE-MRI) exams. Sequences: Pre-contrast (zero-dose), post-contrast after 10% dosage administration (low-dose) and post-contrast after 100% dosage administration (full-dose) was collected with 3D T1 IR-FSPGR sequences for each patient. Method: Different series from the same patient wer corregistered and normalized. A deep convolutional neural network (3D U-Net) was trained to learn the approximation of the full-dose CE-MRI using low-dose and zero-dose images. 5-fold cross-validation was used to generate results for evaluation. Evaluation: Quantitatve metrics (PSNR, RMSE, SSIM) were used to evaluate the improvement of the enhanced contrast using deep learning. Qualitative metrics (image quality, contrast enhancement quality) were used to evaluate the result of the DL based enhancement. A non-infereiority test was conducted to demonstrate the performance of the method and validate the capability of reducing dosage without image quality loss.

RESULTS

Quantitative metrics demonstrated consistent (~4dB in PSNR and 10% in SSIM) and significant ($p<0.001$) quality improvement of the deep learning based solution, compared with low-dose CE-MRI. Qualitative ratings showed non-significant differences between the proposed method and acquired full-dose CE-MRI images, which was also verified with the non-inferiority testing. Initial results also demonstrated the possibility of synthesizing full-dose CE-MRI images with zero-dose MR images only.

CONCLUSION

With a large dataset, we demonstrated the DL solution can generalize well, achieving robust and significant quality improvement over the low-dose CE-MRI, using 10% or even less gadolinum dosage. It enables significantly (at least 10x) gadolinium dosage reduction without sacrificing diagnositic quality.

CLINICAL RELEVANCE/APPLICATION

Deep Learning solution is valuable in clinical radiology for fighting against gadolinium deposition.

PURPOSE

This work reports the implementation and assessment of a novel beam filter to achieve dynamic fluence field modulation (FFM) on x-ray CT systems.

METHOD AND MATERIALS

Multiple aperture devices (MADs) are designed and constructed with fine-scale alternating tungsten bars and air gaps to control the local transmission of x-rays. Relative motion between two MADs in sequence yields Moiré patterns permitting a wide range of fluence modulation profiles with small displacements. In physical experiments, dual MADs were combined with view-dependent mAs modulation to achieve phantom-specific FFM for different imaging objectives including, e.g., 1) a minimum mean variance objective to minimizes mean variance in filtered-backprojection reconstruction, and 2) a flat-field objective to homogenize noise in the reconstruction. Novel pre-processing approaches were developed to accommodate ray-dependent physical effects induced by the filters and to provide artifact-free reconstructions. Image quality assessments were performed for an ellipse phantom (25.8x14.1 cm) and a CatPhan sensitometry module.

RESULTS

The dual-MAD module is compact and yields narrow to wide fluence profiles covering 31.2° to 66.5° of the fan beam with just 0.44 mm of relative motion. The augmented pre-processing chain alleviates ring artifacts that are present in conventional gain correction methods while preserving high frequency structures in the phantom. Noise properties associated with the two imaging objectives agree with theoretical expectations, with the flat-field objective producing nearly homogeneous and isotropic noise, and with the minimum mean variance objective yielding the lowest average noise.

CONCLUSION

The dual MAD filter provides an effective approach to deliver dynamic FFM and image quality control for different imaging objectives and variable patient anatomies whereas traditional static bowtie filters cannot accommodate asymmetric patient cross-sections or varying patient size. The small form factor of the MAD system and the sub-mm motion requirement facilitates FFM implementation on clinical CT scanner.

CLINICAL RELEVANCE/APPLICATION

The dual MAD filter facilitates dynamic FFM on diagnostic CT, which allows dose reduction and image quality control customized to the specific anatomy of the patient.

SSC13-02 Imaging With a Full FOV Silicon-Based Spectral Photon-Counting Detector in a Clinical CT Gantry

PURPOSE

A spectral photon-counting silicon edge-on detector with full field-of-view (FOV) has been mounted in a clinical CT gantry and evaluated for imaging. The aim is to demonstrate the benefit of high-resolution spectral photon-counting imaging in a clinical environment.

METHOD AND MATERIALS

The detector is based on high-resolution edge-on silicon-strip sensors. It has 2 slices, 50 cm FOV and is mounted on a clinical GE Lightspeed VCT gantry. The sensors have 8 energy bins that are used for spectral imaging, i.e. material decomposition. The x-ray tube is operated at clinically relevant fluxes.

RESULTS

The small detector pixels allow high-resolution imaging which will be demonstrated on anthropomorphic phantoms. High-resolution image acquisition also allows reducing the image noise for maintained spatial resolution (e.g. matching today's detector with 1mm pixels) and this effect is demonstrated for a soft-tissue imaging task. A demonstration of the spectral capability for separating materials (iodine, calcium and soft-tissue) is presented. Count-rate and pile-up are hot topics for photon-counting detectors in clinical environments. Here, the effect on the image quality when going up in the high-flux regime is demonstrated. It will be shown that the high-speed ASIC, together with the small pixels and the segmented edge-on design, is capable of handling very high count-rates without significant loss of image quality.

CONCLUSION

Silicon-based spectral photon-counting detectors are promising for use in high-flux clinical CT. The benefits from the higher resolution, better dose efficiency and spectral capabilities could lead to a new era in medical CT imaging.

CLINICAL RELEVANCE/APPLICATION

Photon-counting spectral detectors are emerging for use in clinical CT and the potential advantages are many, including: high-resolution, low-dose capability and full spectral imaging (simultaneous acquisition of more than 2 energies). Many studies have presented results from CZT-based prototype detectors, but this is to our knowledge the first full field-of-view clinical prototype of a silicon-based photon-counting detector. The benefits of silicon as a detector material include: high-resolution, spectral fidelity, count-rate resistance and manufacturability.

SSC13-03 Using 3D Depth Camera for Precise Automatic Patient Positioning in Computed Tomography

Monday, Nov. 26 10:50AM - 11:00AM Room: N230B

PURPOSE

The aim of this study was to evaluate the accuracy of a three-dimensional (3D) camera algorithm for automatic and individualized patient positioning based on body surface detection and to compare the results with manual positioning performed by technologists in routinely obtained chest and abdomen computed tomography (CT).

METHOD AND MATERIALS

This study included data of 120 patients undergoing clinically CTs. 52 patients were scanned with CT using a table height manually selected by technologists; while other 68 were automatically positioned based on patient-specific body surface and contour detection. The ground truth table height was defined as the table height that aligns the axial center of the patient's body and the scanner isocenter. Off-centering was defined as the difference between the TGT and the table position actually used the CT. The t-test was performed to determine the significance of the differences in the vertical offset when automatic vs manual positioning was used. Chi-square test was used to check whether there was a relationship between patient size and the magnitude of off-centering.

RESULTS

We found a significant improvement in patient centering (offset of 5±3 mm) when using the automatic positioning algorithm with the 3D camera compared to manual positioning (offset of 19±10mm) performed by technologists ($p<0.005$). The absolute maximal offset was 39 mm and 43 mm for chest and abdomen CT, respectively, when patients were positioned manually, while with automatic positioning using the 3D camera the offset did not exceede15 mm. In chest CTs with manual patient positioning, the Chi-square test has shown the significant statistical correlation between the vertical offset > 20 mm and the patient size (BMI > 26 kg/m2)

(p<0.001). While in case of abdomen examinations this relationship was found to be insignificant (p=0.38).

CONCLUSION

The study indicates that automatic patient positioning using an algorithm based on 3D patient surface detection provides better patient centering as compared to manual positioning performed by technologist.

CLINICAL RELEVANCE/APPLICATION

Automatic individualized patient positioning can be successfully applied in the clinical routine for accurate patient positioning and in better radiation dose utilization.

SSC13-04 X-ray Induced Acoustic Computed Tomography (XACT): A Novel Technique for Low-Dose, High-Resolution, CT imaging

Monday, Nov. 26 11:00AM - 11:10AM Room: N230B

PURPOSE

We are developing a low-dose, high resolution imaging modality, x-ray induced acoustic tomography (XACT). This novel technique can yield 3D x-ray bone density images via a single projection of a pulsed x-ray, therefore considerably lowering patient dose. In addition, XACT resolution is higher than that of conventional CT, with expected resolutions in the range of 100um.

METHOD AND MATERIALS

In XACT, a pulsed x-ray beam is absorbed by a sample. The absorbed x-ray energy is converted into heat and the subsequent thermoelastic expansion results in the emission of a detectable ultrasound (US) signal. This US is a spherical wave, and so yields 3D information. The detected signal can be used to compute the x-ray absorption, and important 3D clinical information. We have constructed an XACT imaging system, which previously imaged a lead sample We have extended the imaging capability of this system to biological samples and have acquired a signal from a chicken bone. We have optimized the signal generation, detection, and image reconstruction of this system. We aim to image biological samples using XACT and a transducer array to maximize imaging speed and utility.

RESULTS

We have obtained a signal and an image from a biological sample (chicken bone). We have also demonstrated the capability of XACT to image in vivo samples at a lower dose than that of conventional CT with higher imaging resolution. These promising results demonstrate that XACT is a viable imaging modality with high potential for clinical translation.

CONCLUSION

The high potential for clinical translation of XACT has been demonstrated. XACT allows for the high-resolution imaging of x-ray absorption at much lower doses than conventional x-ray imaging techniques. We believe that the clinical translation of XACT is possible, and can revolutionize x-ray imaging by providing 3D information with a single projection and at lower doses than that of conventional CT.

CLINICAL RELEVANCE/APPLICATION

XACT can obtain 3D x-ray absorption images via a single x-ray projection onto a sample. Therefore, the dose in XACT is substantially lower than that of conventional CT. The imaging versatility of XACT is on par with that of conventional CT, including 3D imaging capability of the breast and bone. However, XACT can perform this imaging at comparable resolutions without the need for scanning throughout the sample. This yields substantial improvement in both imaging speed and dose reduction.

SSC13-05 Artificial Neural Network Based Prediction of Contrast Agent Injection Parameters Using Real Time Test Bolus Information

PURPOSE

Optimization of contrast agent (CA) administration protocols is a crucial component of medical imaging to obtain diagnostic quality images. Here we aim to develop an artificial neural network (ANN) framework to predict the required contrast injection parameters to achieve a desired contrast enhancement (CE) in a given organ (kidney in this study) based on test bolus (TB) information.

METHOD AND MATERIALS

Synthetic data was used to feed and train a machine learning model to predict patient-specific CM injection protocol for a desired enhancement in different organs. Applying a validated perfusion model and tweaking the different patient-specific parameters (50 total) such as age, sex, cardiac output, and organ and vessel sizes, as well as injection protocol parameters such as iodine concentration (270, 300, 320, and 350 mg/ml), volume (100, 115, 130, and 140 ml), and injection rate (2, 3, 4, 5, and 6 ml/s), we generated 4000 CE data in kidney. TB curves were generated using the same concentrations and constant rate of 5 ml/s and volume of 10 ml. Data were split into training and test sets (split factor 0.2), and an ANN regression model was trained. For 800 given kidney peak enhancement and time to peak, injection parameters were predicted.

RESULTS

To obtain the given CE in kidney (i.e., time-to-peak and peak enhancement) for individual patients, mean absolute percentage error in prediction of the main injection parameters, concentration, injection rate, injection time, and contrast volume were 3%, 4%, 8% and 9%, respectively. The mean error of the prediction model without including the TB information, was higher than the results reported above by maximum of 4%. Using the predicted parameters, the mean error for both time-to-peak and peak enhancement for kidney was less than 5%.

CONCLUSION

Our results showed that, in absence of enough clinical perfusion data from different organs, by using synthetic data from a validated perfusion model, in addition to the test bolus information, we could train an AI model to offer the required CA administration parameters in order to obtain the desired CE in any targeted organ or vessel.

CLINICAL RELEVANCE/APPLICATION

This technique offers the possibility to determine patient-specific contrast material injection parameters to provide higher accuracy and consistency in the way that contrast enhanced CT examinations are performed.

SSC13-06 Pre-Clinical Demonstration of Grating-Based Phase Contrast X-Ray Imaging for Cryoablation Therapy

shanblatt.elisabeth@mayo.edu

PURPOSE

Cryoablation, often guided by CT or MRI, is an important tool in the treatment of cancer and other conditions. This work uses phase contrast imaging (PCI) to detect temperature changes, demonstrating cryoablation as a potential application for PCI.

METHOD AND MATERIALS

Experiments were carried out using fresh pork loin obtained from a local grocer. The PCI system was a Talbot-Lau grating-based interferometer designed for 27 keV X-rays. Images with attenuation, phase, and dark field contrast were obtained. The first experiment tested whether temperature changes could be detected by each contrast mechanism. We imaged a porcine sample after it froze overnight in a -60°C freezer, and then again after thawing. In a second experiment, we tested if we could detect temperature changes induced by a cryoprobe. We imaged a porcine sample after forming an ice-ball with a cryoprobe (Galil Medical, IceSeed 1.5 MRI Needle). Prior to imaging, the sample was subjected to a 15 min. freeze followed by a partial thawing until the probe could be removed from the sample.

RESULTS

The addition of phase and dark field contrast mechanisms provided structural detail and good temperature differentiation. Histograms showing the distribution of values in the CT phase reconstruction vs. the CT attenuation reconstruction (voxel size 54x54x54 µm) show a larger change in signal between the frozen and thawed pork. This result is consistent with theory: for water imaged with 27 keV photons, the change in attenuation of 54 µm of liquid vs. frozen water is expected to be about 0.02%, whereas the change in phase is expected to be about 38%. Our data show that the mean attenuation changed by 3%, and the mean phase changed by 34%. Histograms of values from a projection image of the cryoablated pork qualitatively demonstrate that the dark field signal is more sensitive to temperature change than the attenuation signal, even for a small amount of thawing that took place over 46 min.

CONCLUSION

We demonstrated that PCI has potential application for temperature monitoring during cryoablation procedures. Phase and dark field contrast are very sensitive to interfaces and density changes, making them ideal for imaging temperature-sensitive processes.

CLINICAL RELEVANCE/APPLICATION

Cryotherapy is used in a wide variety of treatments, and phase and dark field information can be used to sensitively monitor cryogenic and other processes during surgery.

SSC13-07 Three-Dimensional CT Scout from Conventional Two-View Radiograph Localizers Using Deep

Learning

jcmontoya@wisc.edu

PURPOSE

The purpose of this work was to develop a deep learning-based image reconstruction framework to enable the reconstruction of volumetric 3D scout CT images from the conventional two-view (lateral and AP) projection scout radiographs.

METHOD AND MATERIALS

751 clinically indicated chest-abdomen-pelvis (CAP) CT exams from 667 patients were retrospectively collected. Inclusion criteria were: 1. CT exams acquired with or without contrast media and 2. Either one of the following 6 scan coverages: chest-alone, abdomen-alone, pelvis-alone, chest-abdomen, abdomen-pelvis or CAP. To avoid potential data inconsistency, large patients (>50 cm lateral width) with significant truncation were excluded. CT image volumes were interpolated to a 1.0x1.0x1.0 mm3 isotropic voxel size and registered to the 2D scout radiographs using the patient positioning information in the DICOM header. A total of 163,840 CT images with 1120 radiograph localizers from 476 patients were used to train a 60-layer deep neural network which inputs the AP and lateral localizers and outputs a volumetric CT scout; 47,919 CT images with 382 radiograph localizers from 191 patients were used for testing and validation. To test the generalization error of the trained deep neural network, a Monte Carlo dose calculation of an axial CT scan was performed in three anatomical regions using both the diagnostic CT images and the 3D-scout of one subject. Gamma analysis with 10%/5mm dose-difference/distance-to-agreement criteria was performed to compare both radiation dose distributions.

RESULTS

The average gamma indices between the diagnostic CT and the 3D-scout images were 0.33, 0.37 and 0.34 for anatomical regions in the chest, abdomen and pelvis, respectively. Similarly, the percentages of voxels with passing gamma index ($\gamma<1$) were 97.3%, 97.3% and 98.2% for the three anatomical regions.

CONCLUSION

A deep learning method was developed to reconstruct volumetric scout CT images from two-view projection scout radiographs. The proposed method could enable more accurate radiation dose estimates and scanning parameter prescription prior to CT acquisition and thus potentially help overcome limitations of automatic exposure control schemes in diagnostic CT.

CLINICAL RELEVANCE/APPLICATION

The reconstruction of 3D-scouts from two-view localizers could revolutionize the prescription of radiation dose/image quality in diagnostic CT, enabling the next generation of intelligent CT scanners.

SSC13-08 Stopping Power Ratio (SPR) Uncertainty in Pencil Beam Scanning (PBS) Proton CT (pCT) Reconstruction: Dependency on Energy Straggling and Detector Energy Resolution

zhouj995@hotmail.com

PURPOSE

To investigate the effect of proton energy, energy straggling (ES), and detector energy resolution (DER) on the uncertainty of the SPR reconstruction in PBS pCT reconstruction.

METHOD AND MATERIALS

A Monte-Carlo model was developed based on PBS technology to simulate the pCT acquisition. An 8cm-diameter cylinder water phantom was used in the simulation, filled with three 2-cm cylinders comprised of ICRU bone, muscle, and adipose, respectively. 180 projections were generated with 252 spots (500 protons/spot) on each projection. Spot spacing and size on the detector were 5.4mm and 6mm, respectively. Simulations were conducted w/wo energy ES fitted to real clinical 120 and 200 MeV proton beams. DER were set to 2% and 10%, in order to simulate detector uncertainty in the measurement of proton residual energy. Mean and standard deviation (STD) of SPR within the background and the three cylinders were calculated.

RESULTS

Total dose to the phantom was<.4mGy. The reconstructed mean RSP for both w/wo ES were the same: .995(-.5%), .968(-.2%), 1.026(-.4%), and 1.702(-1.0%) for the water, adipose, muscle, and bone, respectively. The STDs of the reconstructed RSP

were<.006 for all energies when DER=2%. With DER=10%, the STD of reconstructed RSP at 200 MeV was significantly higher(.01 vs .006, p<.05).

CONCLUSION

As PBS pCT derives projection images from statistical analysis of PBS spots, it is not sensitive to variations in proton ES and DER up to 10%. This is the first study to demonstrate the PBS proton beams being used directly for RSP reconstruction with significantly less dependency to ES and DER. Further technology development is warranted and is in process to improve the image resolution and the RSP accuracy for small regions of interest.

CLINICAL RELEVANCE/APPLICATION

Although proton radiography was first reported 5 decades ago, there is yet a commercial product to be developed given proton's multi-coulomb medium scattering, the cost of the proton CT, and furthermore the complicated single proton tracking technique used in the current passive scattering based pCT devices. In this study, we report the very first relative stopping power (RSP) reconstruction based on PBS technology and statistical processing of protons within each spot. This novel pCT acquisition and reconstruction methods could be efficient and effectively implemented into a routine clinical proton PBS machine with the capability of pre-treatment and intrafraction imaging.

SSC13-09 Dual Source Photon-Counting-Detector CT with a Tin Filter: A Phantom Study on Iodine Quantification Accuracy and Precision

leng.shuai@mayo.edu

PURPOSE

To evaluate the impact of a multi-source photon-counting-detector (PCD) CT configuration, including the use of a tin filter and increased number of energy bins, on iodine quantification.

METHOD AND MATERIALS

olllA multi-energy CT phantom (Sun Nuclear) with iodine inserts at concentrations of 0, 2, 5, 10, 15 mg/mL was scanned on a research PCD-CT system with one source/PCD array. A reference scan was performed with 140 kV, 2 energy thresholds (TL and TH) and 32 mGy CTDIvol. Various multi-source PCD configurations were emulated by performing separate scans with different tube potentials and energy thresholds. Scans were performed at tube potentials of 80, 100, 120, 140, and Sn140 kV (140 kV with a tin filter), and multiple-source configurations using all possible kV pairs were investigated. Tube current was adjusted so that the CTDIvol of each scan was half of the reference scan (16 mGy) so that the total radiation dose was matched for all scan combinations (32 mGy). For each kV pair, two scenarios were investigated: (1) dual-energy scan with only 1 energy threshold (TL) used from each detector; and (2) quad-energy scan with 2 energy thresholds used from each detector. Images were reconstructed using standard filtered backprojection. Image-based material decomposition was performed to generate iodine and water maps. Root mean square error (RMSE) was measured for all iodine inserts and for each kV and energy threshold combination.

RESULTS

Among dual-energy configurations, 80/140 had the lowest RMSE of iodine concentration, 14.7 mg/mL, which was lower than that of reference scan using 140 kV (15.8 mg/mL). The use of a tin filter reduced the RMSE to 10.2 mg/mL. The lowest RMSE, 9.1 mg/mL, was achieved with the quad-energy configuration. Use of 4 energy thresholds (instead of 2) reduced RMSE by 20-75% for the kV pairs of 100/140 and 120/140.

CONCLUSION

Performance of PCD-based multi-energy CT can be substantially improved using a multiple source configuration, a tin filter and multiple energy thresholds, with a 42% reduction of RMSE (15.8 to 9.1 mg/mL) in iodine quantification accuracy observed through phantom studies.

CLINICAL RELEVANCE/APPLICATION

Dual-source PCD-CT with a tin filter can potentially provide better image quality, more accurate material quantification and lower dose than that of single-source PCD-CT.

PURPOSE

SRS is commonly utilized as a definitive therapy in patients with unresected large brain metastases (BrM), as it provides excellent rates of 1-year local control (LC); however, resultant radionecrosis (RN) is a known risk. fSRS is a treatment option intended to reduce the incidence of RN and improve LC in these patients. There is a paucity of prospective data comparing these two modalities; therefore, a meta-analysis of existing retrospective and prospective studies was conducted.

METHOD AND MATERIALS

The co-primary outcome measures were incidence of RN and LC at 1 year. Large BrM were defined according to Radiation Therapy Oncology Group 90-05, where Group A: 2-3 cm diameter (4-14 cc volume) and Group B: >= 3 cm diameter (>14 cc volume). PICOS/PRISMA/MOOSE guidelines were used to select studies where patients with large BrM: (1) RN rates and/or 1-year LC were available; (2) SRS and/or fSRS were administered as treatment for unresected metastases; (3) data regarding tumor size were reported. Weighted random effects meta-analyses were used to analyze RN and 1-year LC. Fractionation and size were analyzed as moderators using analysis of variance and omnibus test where the null hypothesis was rejected for $p<0.05$.

RESULTS

A total of 17 studies conducted from 1998-2016, in 6 nations, consisting of 1,007 large BrM, met inclusion criteria. Median patient age was 62 years, median follow up was 9.5 months, and the most commonly used radiosurgery platform was Gamma Knife (9/17 studies). The range of SRS doses was 15-20 Gy, and the range of fSRS doses was 24-35 Gy in 2-5 fractions. The most common SRS dose was 18 Gy/1 fraction, and the most common fSRS dose was 27 Gy/3 fractions. Incidence of RN at 1-year for all studies was 9.2%; and was 18.2% for SRS and 6.7% for fSRS, $p=0.008$. 1-year LC for all studies was 79.3%; and was 74.0% for SRS and 83.4% for fSRS, $p=0.20$. By tumor volume, the incidence of RN in Group A was 10.5% and in Group B was 7.7%, $p=0.51$. 1-year LC in Group A was 86.2% and in Group B was 76.3%, $p=0.07$.

CONCLUSION

Among patients with unresected large BrM treated with radiosurgery, fSRS is associated with decreased rates of RN and potentially improved 1-year LC compared to SRS.

CLINICAL RELEVANCE/APPLICATION

Fractionated stereotactic radiosurgery (fSRS) is a recent advancement in radiosurgery, although its relative safety and efficacy compared to single fraction stereotactic radiosurgery (SRS) is unknown.

SSC14-04 The Dancing Cord: Inherent Spinal Cord Motion and Its Effect on Cord Dose in Spine Stereotactic Body Radiation Therapy

PURPOSE

Adherence to strict dose limits is critically important in stereotactic body radiation therapy (SBRT) for spine tumors to reduce the risk of neurologic complications. Validated dose constraints have been established. However, inherent motion of the spinal cord has not yet been explored with respect to dosimetric effects in spine SBRT.

METHOD AND MATERIALS

Dynamic cardiac-gated balanced fast field echo MR imaging was obtained as part of routine treatment planning imaging for VMAT-based spine SBRT in 8 patients with spine tumors. Imaging and dosimetric data were analyzed in a retrospective IRB approved study. Planning CT data sets, static T2-weighted (cordstat), and each of 15 phases of the dynamic MRI images (corddyn) were coregistered. Cord deformation and motion on the dynamic imaging was compared to the static T2-weighted images, with respect to cord area, Dice coefficient, Jaccard index and excursion of the corddyn beyond the cordstat and planning organ at risk volume (PRV) margins. Dose was compared between cordstat, and corddyn. Comparisons were made using the Wilcoxon signed rank test.

RESULTS

The cross-sectional areas were not significantly different between cordstat and corddyn (0.51±0.12 vs. 0.52±0.13 mm2, p=0.814), suggesting no major cord deformation. Assessing cord motion, Dice coefficient between cordstat vs. corddyn ranged from 0.70 to 0.96 (mean, 0.85±0.05). Jaccard index ranged from 0.54 -0.92 (mean, 0.75±0.08). In 4 of the 8 patients, the maximal dose to corddyn exceeded that of cordstat by 1.2 - 12.8% (mean 5.2±4.3%). The corddyn spatially moved outside the 1 mm PRV margin of cordstat in 4 of the 8 patients: 13% of the time in 2, and 27% of the time in 2 patients. Corddyn did not extend outside the 2 mm PRV margin of cordstat.

CONCLUSION

The spinal cord shows inherent motion, resulting in measurable dosimetric effects which should be considered during SBRT dosimetry. A PRV margin of 2 mm surrounding the cord is suggested to account for the inherent spinal cord motion.

CLINICAL RELEVANCE/APPLICATION

Accurate imaging of the spinal cord is critical to assure dose limits and prevent neurologic complications in patients receiving high-precision/high-dose stereotactic body radiation for spine tumors.

SSC14-05 Two-Fraction Radiosurgery (9Gy x 2) is an Effective and Safe Option in the Modern Era of CNS Penetrating Systemic Therapies

PURPOSE

In the era of CNS-penetrating systemic therapies, stereotactic radiosurgery (SRS) has resulted in higher intracranial control rates

in the era of CNS-penetrating systemic therapies, stereotactic radiosurgery (SRS) has resulted in higher intracranial control rates as well as higher rates of radionecrosis. We sought to determine if lower biologically equivalent dose SRS, specifically 18Gy in 2 fractions (fx), can achieve adequate local control with reduced adverse events.

METHOD AND MATERIALS

We retrospectively reviewed patients who received SRS in our department from 2014-2015. In this period, we had implemented a fractionated SRS regimen of 18Gy in 2fx for >3 simultaneously treated lesions, with all lesions typically being <2 cm which some exceptions. Median GTV-PTV expansion was 2mm (range 0-5mm). Dose was prescribed to the periphery to the 65-90% isodose line. We documented lesion location, prior radiation, volume, largest single dimension, and if symptomatic radionecrosis occurred. Cancer subtype, systemic therapies, cause of death, and performance status was included as well. Cox proportional hazards models were used to determine factors affecting local control.

RESULTS

From 2014-2015, we treated 242 lesions from 59 patients using stereotactic radiosurgery. Within this cohort, 126 lesions from 27 patients were treated using 18Gy in 2fx. 22 of 27 patients treated using these two fraction regimens were followed until death. The majority of lesions of the two-fraction cohort came from a melanoma primary (n=94). Ten lesions were resected before SRS. For the two fraction regimen, local control was 59% at 1-year, and 59% at 2-years. Radionecrosis occurred in 2 lesions (1.6%). The majority of lesions (n=88) were <1cc, 35 were 1-10cc in volume, and the remaining 3 were 10-98cc in volume. On multivariate analysis of the entire cohort, maximum single dimension, and prior surgical resection were independent predictors of local failure. Number of fractions was not significantly associated with local failure.

CONCLUSION

In our cohort, 18Gy in 2fx delivered acceptable local control with very low rates of symptomatic radionecrosis.

CLINICAL RELEVANCE/APPLICATION

Lower-dose, two-fractionation radiosurgery may be appropriate for patients with high volume disease, poor performance status or patients receiving central-nervous system penetrating systemic therapies.

SSC14-06 T2WI Histogram Analysis for Differentiating Glioblastoma from Solitary Brain Metastasis

Monday, Nov. 26 11:20AM - 11:30AM Room: E353A

Participants

PURPOSE

To study the value of T2 gray histogram analysis of differential diagnosis in glioblastoma and brain solitary metastasis.

METHOD AND MATERIALS

A retrospective analysis was conducted by brain MRI examination and pathology diagnosis of 57 cases of glioblastoma and brain solitary metastasis in our hospital .Among them, there were 29 cases of glioblastoma(there were 17 males and 12 females), 28 cases of astrocytoma(there were 15 males and 13 females).Respectively, to draw the region of interest(ROI) in the T2 MR transaxial images of two groups on maximum layer of tumor level by using Mazda software and analyze the whole tumors gray histogram, performing a statistical analysis on the two sets ofparameters obtained from histograms to find out statistical significance of each parameter.The kurtosis, skewness, the first percentile, the 10th percentile and the 90th percentile were in accordance with the normal distribution. Two independent samples t-test were used to compare the differences.Mean , Variance, the 50th percentile, the 99th percentile did not fit the normal distribution, using nonparametric test, P <0.05 was statistically significant.

RESULTS

Through histogram analysis of 9 parameters, these 7 parameters were statistically significant (all P <0.05),including mean , kurtosis,skewness, perc.10%,perc.50% ,perc.90% and perc.99%. Among them,the sensitivity of skewness was 82.1%, the specificity was 82.8%, the area under the curve was 0.865,and the best cut-off value was 0.58.

CONCLUSION

The T2WI gray histogram analysis is helpful for the identification of brain solitary metastasis from glioblastoma and the skewness has a high diagnostic efficiency.

CLINICAL RELEVANCE/APPLICATION

The T2WI gray histogram analysis is helpful for the identification of brain solitary metastasis from glioblastoma.

SSC14-08 18F-FDOPA PET/MR Based Target Definition in the 3D Based Radiotherapy Treatment of Glioblastoma Multiform Patients: Early Results of a Single Institute Study

PURPOSE

In the staging and 3D radiotherapy planning process of glioblastoma multiforme (GBM) patients conventional MRI plays important role. The 18F-F-DOPA positron emission tomography (PET) imaging utilising metabolic radiotracers for better evaluation of the affectet area by the tumor. 18F-FDOPA penetrates into the cells by a process mediated by amino acid transporters and demonstrates higher sensitivity and specificity for gliomas than traditional 18F-FDG PET and contrast enhanced MRI imaging. Our aim was to present the feasibilty of this amino acid tracer in modern 3D radiotherapy planning.

METHOD AND MATERIALS

We present a retrospective analysis of the PET/MR based planning study with 18F-FDOPA in 4 patients with histologically proven GBM. In the contouring process The native planning CT scanes were fused with the PET/MR series (T1 contrast enhanced, T2 and 18F-F-DOPA sequences). We defined 18F-F-DOPA uptake volumen (BTV-F-DOPA), the T1 contrast enhanced MRI volume (GTV-T1CE), and the volume of area covered by oedema on the T2 weighted MRI scan (CTV-oedema) in all patients. We also registered the volume BTV-F-DOPA volumes not covered by the conventional MR based target volumes.

RESULTS

The mean 18F-F-DOPA tumor volumes was 37,1 cm3 (range 15,3-80,3; SD=29,48). The mean GTV T1 CE was 7,2 cm3 (range 2,6-13,2; SD=4,89). The mean CTV oedema volume was 57,4 cm3 (range 27,7-108,8; SD=36,49). The mean volume of the BTV-F-DOPA not covered by the CTV oedema volume was 8,6 cm3 (range 1-21; SD=9,22).

CONCLUSION

Based on our results the tumor area defined by the amino acid tracer is not fully identical with MRI defined T2 oedema CTV. 18F-FDOPA defined BTV can modifie the definiton of the PTV, and the radiotherapy treatment.

CLINICAL RELEVANCE/APPLICATION

18F-FDOPA PET/MR based target definiton in the 3D based radiotherapy treatment will provide better tumour extension characterization of patients suffering from glioblastoma multiforme.

PURPOSE

To evaluate the safety and effectiveness of Magnetic Resonance guided Focused Ultrasound (MRgFUS) ablation in patients with organ-confined intermediate risk prostate cancer in order to postpone or eliminate the need of definitive treatment (i.e. Radical Prostatectomy or Radiation therapy).

METHOD AND MATERIALS

This prospective single-arm study enrolled 19 patients, aged 50-74 years, with histologically proven organ-confined intermediate risk prostate cancer. Inclusion criteria for participation: Gleason score <= 7 (=3+4 or 4+3, no grade 5 pattern), T1-T2b, N0, M0 stage, PSA <= 20 ng/ml, lesion visible to dynamic contrast enhanced (DCE) MR imaging and no previous prostatic surgery, radiation therapy or androgen deprivation therapy. All patient underwent pre-treatment DCE (Gd-BOPTA, Bracco) MR examination (Discovery 750, GE) and MRgFUS treatment with ExAblate (InSightec). Safety of treatment was determined by evaluation of the incidence and severity of device related complications while clinical efficacy was evaluated monitoring MR imaging changes and PSA levels at 3, 6 and 12-months.

RESULTS

1 patient reported urinary incontinence while 2 patients referred erectile dysfunction after MRgFUS treatment. DCE MR imaging at 3, 6 and 12 months showed no recurrence/residual disease in treated patients. According to imaging, laboratory exams showed a progressive decrease of PSA level from an average value of 17,1 ng/ml before treatment to 2,2 ng/ml at 12 months follow-up. No one patient needed definitive treatment so far and can be considered free of clinically significant prostate cancer.

CONCLUSION

MR guided Focused Ultrasound appears as a safe and effective treatment for patients with organ-confined intermediate risk prostate cancer and can reduce the need of definitive treatment (i.e. Radical Prostatectomy or Radiation therapy).

CLINICAL RELEVANCE/APPLICATION

MRgFUS can reduce the need of surgery or radiation therapy in patient with intermediate risk prostate cancer representing a safe and effective treatment.

SSC15-02 Magnetic Resonance-Guided Focused Ultrasound (MRgFUS) Focal Treatment of Localized Prostate Cancer: Initial Experience and Follow Up from a Multi-Center Trial

PURPOSE

To evaluate the initial experience, safety and feasibility of MR targeted focused ultrasound treatment of localized prostate cancer

METHOD AND MATERIALS

Patients with biopsy proven prostate cancer enrolled in a prospective multi-center pivotal trial of the ExAblate 2100 prostate system. Eligibility criteria include men of 50 years or older, PSA < 20 ng/mL with either low or intermediate risk prostate cancer (Gleason Score 3+3, 3+4 or 4+3). A multi-parametric MR must confirm localized prostate cancer (Stage T1-T2) and tumor distance ≤ 4cm from rectal wall. All men are treated in 1.5 or 3T GEHC MR devices

RESULTS

38 eligible men have been enrolled and treated from 7 sites. Mean age 62.8 years, mean PSA 6.0ng/mL. Prostate MR demosntrated dominant lesions in 32 men, no lesion in 4 men and MR data was not availaible in 2. Pre-treatment prostate biopsy results showed Gleason 3+3 in 14, 3+4 in 19 and 4+3 in 9. All men successfully underwent MRguided FUS ablation of their focal lesion. All except one were discharged home later on the treatment day. Currently 6 men have completed follow up, 34 men are at 9 months, 27 at 12 and 12 at 18 months. There were 131 combined device or protocol related adverse events, which were Grade 1 (mild) in 117, Grade 2 (moderate) in 13 and Grade 3 (severe) in 1 (severe suprapubic pain 1 week post treatment, resolved the following day without permanent injury). Overall 77 events were procedure related, 48 were transient, 5 biopsy related and 1 device related.

CONCLUSION

Initial experience indicates that MRgFUS appears to be both feasible and safe. Enrolling men in a trial using image-gided focal therapy in prostate cancer is feasible. Accural is ongoing in this pivotal trial.

CLINICAL RELEVANCE/APPLICATION

MR guided Focused ultrasound focal prostate cancer ablation is both safe and feasible.

SSC15-03 Uterine Artery Embolization with Gelfoam for Acquired Symptomatic Uterine Arteriovenous Shunting After Gynecologic Procedures and Obstetric Events

PURPOSE

To evaluate the technical and clinical success rates and safety of bilateral uterine artery embolization (UAE) with gelfoam for symptomatic acquired uterine arteriovenous shunting presenting after obstetric or gynecologic events.

METHOD AND MATERIALS

In this HIPAA-compliant, IRB approved retrospective study with a waiver of informed consent, consecutive patients of reproductive age that presented with abnormal uterine bleeding after recent gynecologic procedure or obstetric event between 01/2013 and 02/2018 at tertiary referral center were included. Bilateral uterine artery embolization was performed in all patients using gelfoam slurry. Technical success was defined as angiographic resolution of AV shunting at the end of the procedure. Clinical success was defined as cessation of bleeding, resolution of findings on subsequent imaging, or minimal estimated blood loss (<50 cc) on a subsequent dilation and curettage procedure.

RESULTS

Eighteen patients (mean age 32.8±7.1y) were included in the study. In one patient coil embolization was used in addition to

gelfoam due to the size of the shunt. Another patient underwent a repeat UAE due to evidence of clinical and sonographic residual RPOC with subsequent technical and clinical success. Angiography demonstrated AV shunting in 18/18 (100%) with early venous drainage from the uterine arteries to internal iliac and / or gonadal veins. 7/18 (38.9%) patients underwent subsequent scheduled D&C due to remaining RPOC with EBL of 17.9 ± 15.6mL. No additional procedures were required. The technical success rate of gelfoam UAE was 17/18 (94.4%) and clinical success rate was 94.1% (16/17). There was 1/18 (5.6%) minor complication of a small groin hematoma that resolved without additional treatment and 1/18 (5.6%) asymptomatic mild pulmonary embolism (PE) detected on CT three days after a procedure,in a patient with history of PE. The average length of clinical follow-up after the UAE procedure was 18.9 ± 15.9 months. 38.8% (7/18) of the patients became pregnant during the follow up.

CONCLUSION

Uterine artery embolization with gelfoam slurry for symptomatic uterine arteriovenous shunting has a high technical and clinical success rate and low potential risk of pulmonary embolism.

CLINICAL RELEVANCE/APPLICATION

Uterine artery embolization with gelfoam slurry only is successful in treating symptomatic uterine arteriovenous shunting and can be used as an alternative to permanent embolization agents.

SSC15-04 Effect of Pelvic MRI on Clinical Management of Suspected Symptomatic Uterine Fibroids

PURPOSE

We aim to determine the impact of pre-procedural pelvic MRI on the clinical management and treatment of suspected symptomatic uterine fibroids.

METHOD AND MATERIALS

An IRB-approved retrospective study of 100 patients referred to Interventional Radiology (IR) for management of suspected symptomatic uterine fibroids between 2013 and 2017 was compiled. Electronic medical records and relevant imaging in PACS were analyzed for patient age, race, gynecological evaluation including pelvic ultrasound results, as well as therapeutic plan prior to and following MRI.

RESULTS

Of the 100 patients who underwent MRI related to IR consultation, 73 patients had previously had a pelvic US. MRI results definitively changed management in 20 patients. Of these, 4 patients had imaging characteristics concerning for malignancy, of which two had completed work-up at the time of this study with a negative endometrial biopsy and a benign teratoma, respectively. Three patients received a new diagnosis of adenomyosis, and the offered treatment plan shifted to uterine artery embolization (UAE) as adenomyosis is best treated with smaller embolic particles. An additional 13 patients were advised not to undergo uterine fibroid embolization (UFE) alone with alternatives pursued including myomectomy (n=3), myomectomy then UFE (n=1), hysterectomy (n=2), hysteroscopy with dilation and curettage (n=1), conservative management (n=1), or referral back to Gynecology prior to final decision making (n=4). An additional patient (n=1) pursued UFE despite recommendation of myomectomy vs. hysterectomy. Fibroid location and vascularity (n=9) was the most common reason for change in plan as devascularized fibroids were felt to be unlikely to respond to endovascular therapy.

CONCLUSION

Pre-procedural evaluation of suspected symptomatic uterine fibroids differs across various clinical settings. We demonstrate a significant impact of pre-procedural MRI in the evaluation of patients: 1 in 5 patients in our small sample had a change in clinical management, and 1 in 25 demonstrated imaging findings concerning for a malignancy not previously identified by pelvic US. MRI should be incorporated into the routine work-up of patients with likely symptomatic uterine fibroids.

CLINICAL RELEVANCE/APPLICATION

MRI offers invaluable information in the work-up of patients with suspected symptomatic uterine fibroids, can alter treatment planning, and can identify previously undiagnosed malignancy.

SSC15-05 Prostate Multiparametric Magnetic Resonance May Avoid Biopsies in Patients with Elevated PSA and Surgical Indication for Prostatic Enlargement Treatment

PURPOSE

to evaluate the performance of mpMRI using PIRADS score on men with surgical indication for BPH and elevated PSA levels, comparing it with TRUS-guided biopsy results.

METHOD AND MATERIALS

Retrospective analysis of consecutive men with BPH and surgical candidates and concomitant elevated PSA levels (>=4ng/mL or >=2g/mL if in use of 5 alpha-reductase inhibitor), from June 2016 to August 2017. All patients were submitted to mpMRI prior to TRUS biopsy. Prostate mpMRI was done using a 1.5-T scanner (GE 350™) without endorectal coil including high resolution T2 weighted (T2W), diffusion weighted imaging (DWI), and dynamic post-contrast enhanced sequences. .Systematic 14-core biopsies were performed and in cases where mpMRI was classified as PIRADS 3 with focal lesions, PIRADS 4 or PIRADS 5, additional 2 to 3 TRUS guided targeted fragments were obtained with fusion technique. Final PIRADS score of mpMRI was compared with biopsy results and transurethral or transvesical resection (when available). Two scenarios were evaluated: first, considering only PIRADS 1 and 2 as negative and second, considering also PIRADS 3 as negative. ISUP >= 2 was was considered as csPCa.

RESULTS

Forty men were included for final analysis, with median age of 68 years, median PSA 6.35 ng/dL and median prostatic volume 116.5 cc. Demographic data are summarized in table 1. Considering the first scenario, the sensitivity, specificity, positive (PPV) and negative (NPV) predictive values of mpMRI for any prostate cancer were 76.9%, 63%, 50%, and 85% respectively. For csPCa the sensitivity was 87.5%, specificity 59.4%, PPV 35% and NPV 95%. For the second scenario, the sensitivity, specificity, PPV and NPV of MP-MRI for any prostate cancer were 53.8%, 96.3%, 87.5%, and 81.3% respectively. For csPCa the sensitivity was 75%, specificity 93.8%, PPV 75% and NPV 93.8%.

CONCLUSION

Negative predictive value of mpMRI was high in patients with surgical indication for BPH and elevated PSA. Our results suggest that patients with PIRADS 1, 2 and 3 could avoid TRUS biopsies before undergoing surgical procedure.

CLINICAL RELEVANCE/APPLICATION

mpMRI may be indicated in patients with BPH and elevated PSA levels with high negative predictive value.

SSC15-06 MRI/TRUS Fusion Guided Focal Laser Ablation for "Super-Active Surveillance" of Prostate Cancer

PURPOSE

Prostate cancer is the most common cancer among men. Standard treatments include radiotherapy and surgery, which may lead to common side effects such as incontinence and impotence. Local focal nerve sparing treatment options often require intraoperative MRI for image guidance, with resulting limitations of cost and MR time, and requiring MR compatible equipment. MRI/TRUS fusion guided transperineal focal laser ablation may address these limitations and provide an alternative method for treating prostate cancer that might otherwise undergo active surveillance.

METHOD AND MATERIALS

A bi-plane endorectal ultrasound probe was attached to an encoded stepper which has two degrees of freedom for rotation about and translation along the probe's physical axis. At the beginning, A 3D ultrasound volume was acquired with a 2D sweep and registered to previously acquired T2w MRI. MRI/TRUS fusion was co-displayed on both transverse and longitudinal ultrasound planes. Pre-segmented MRI tumors were projected on the stepper's grid template in custom software to facilitate treatment planning. Thermocouples were placed at locations near the rectum, urethra, nerve, and bladder if needed. For each ablation, the physician picked a grid hole to insert an introducer. The software predicted the ablation zone based on the grid location and the insertion depth on longitudinal ultrasound. A side-firing laser fiber with a cooling catheter was inserted through the introducer to conduct an ablation for 2 minutes at 9-15 watts. The software estimated the residual tumor, identified regions at risk for under-treatment and planned for the next ablation. This process was iterated until the full tumor was ablated. After the procedure, a T1w contrast enhanced MRI was taken to validate tumor coverage.

RESULTS

Seven patients with a total of 9 tumors were treated. The tumor volume was 1.6±1.3cc. It took 6±2 ablations to treat one tumor. Post-operative MRI confirmed no residual tumor tissue following ablation. One post ablation abscess was observed in a patient without imaging evidence of residual tumor.

CONCLUSION

MRI/TRUS fusion guided focal laser ablation is effective, safe and can serve as a low-cost option for prostate cancer treatment.

CLINICAL RELEVANCE/APPLICATION

The proposed approach may provide a therapeutic option for pre-selected patients with prostate cancer who desire treatment more than active surveillance and less than full organ therapies.

SSC15-07 Outcome of Uterine Artery Embolization for Management of Delayed Bleeding Due to Retained Placenta in Patients with Placenta Accreta

Monday, Nov. 26 11:30AM - 11:40AM Room: E352

Participants

For information about this presentation, contact:

zhiweiwang1981@sina.com

PURPOSE

To retrospectively evaluate the outcome of uterine artery embolization (UAE) for management of delayed bleeding due to retained placenta in patients with placenta accreta (PA).

METHOD AND MATERIALS

A retrospective analysis of the records of all patients diagnosed with PA according to the clinical findings during delivery between January 2005 and December 2017 was performed. Twenty-eight patients were treated conservatively by leaving placenta in place and underwent UAE for bleeding subsequently. The control of hemorrhage, outcome of the placenta left in place, menses and fertility results were retrospectively reviewed.

RESULTS

The mean age was 31.4±6.7 years. Eight patients with massive vaginal bleeding underwent emergency UAE. The other 20 patients presented with intermittent vaginal blood loss and underwent selective UAE. The median time between delivery and UAE was 15 days. The mean retained placental volume obtained by ultrasound was 164±133 cm3.The technical success rate of embolization was 100%. Angiography revealed uterine arteriovenous malformations in two patients. Bleeding was controlled in all patients during follow-up (10.7±7.9 months). The retained placentas were spontaneously passed vaginally or absorbed in 15 patients. Ten patients underwent curettage after UAE. Of these 10 patients, 7 retained placentas were completely removed and 3 retained placentas were partly removed and absorbed later. The other 3 retained placentas were resected for they did not decrease in size significantly after UAE. Menses returned 1-3 months after UAE in all patients and they had regular monthly cycles afterwards. And five patients delivered without complication during follow-up.

CONCLUSION

UAE is safe and effective for management of retained placenta associated with placenta accreta.

CLINICAL RELEVANCE/APPLICATION

Conservative management of the abnormal placenta, which is left inside the uterus at the time of delivery has been more and more used in clinial practice to minimize blood loss after delivery and to preserve the uterus in women with PA. UAE should be consided for subsequetly management of these patients.

SSC15-08 The Relationship of Embolic Particle Size to Patient Outcomes in Prostate Artery Embolization for Benign Prostatic Hyperplasia: A Systematic Review and Meta-Regression

PURPOSE

Prostate artery embolization (PAE) has been proven to be a safe, efficacious and cost-effective treatment for Benign Prostatic Hyperplasia (BPH). There has been much variation in the size of embolic particle agent used in existing studies and the degree of patient outcomes achieved. We aimed to explore the relationship of particle size to patient outcomes.

METHOD AND MATERIALS

A systematic review of MEDLINE, PubMed and Embase was undertaken to identify all existing studies using PAE for BPH. Inclusion criteria included studies reporting a baseline and 12 month International Prostate Symptom Score (IPSS). Exclusion criteria excluded overlapping studies. Data extraction from eligible studies included the size of embolic agent and Baseline and 12 month values for: IPSS, IPSS Quality of Life, Q-max, prostate volume, prostate specific antigen and post-void residual. A weighted linear regression analysis was then used to explore the relationship between particle size and the change in the outcome measures (from baseline to 12 months).

RESULTS

6 non-overlapping studies were identified for data extraction. The linear regression analysis did not demonstrate a statistically significant ($p<0.05$) relationship of particle size with the 12 month change in patient outcome measure. However, smaller particle size and greater reductions in IPSS approached statistical significance ($p=0.08$).

CONCLUSION

Our findings suggest that there is a possible association of smaller particle size with greater reductions in IPSS. Whilst not statistically significant, these findings impress upon the need for further research on determining the optimum particle size for PAE.

CLINICAL RELEVANCE/APPLICATION

Smaller embolic particle size may be associated with greater symptom severity reduction in patients undergoing PAE for BPH.

SSC15-09 Visualization of the Different Branches of the Internal Iliac Artery Before Prostatic Artery Embolization Using Three Dimensional Contrast-Enhanced MR Angiography

Monday, Nov. 26 11:50AM - 12:00PM Room: E352

PURPOSE

To evaluate the ability of Three Dimensional Contrast Enhanced MR Angiography (3D-CE-MRA) in Visualizing the branches of the Internal Iliac Artery (IIA) in males prior to prostatic artery embolization (PAE).

METHOD AND MATERIALS

Pre-embolization CE-MRA studies from 30 males (mean age 68.18 years) were retrospectively evaluated by two radiologists in consensus. Studies were done using a 3 Tesla MRI unit and 3D images were reconstructed using Syngo Vessel View Application. Studies from 2 patients were excluded (due to incomplete coverage of the pelvis). A scoring system of 3 Grades was adopted where a score of 0 means that the artery was not seen, interrupted or its origin could not be identified, a score of 1 means that the artery was faintly seen but can be traced and has no missing segments till it gives off its first branch, finally score 2 means that the artery was clearly seen.

RESULTS

Of the studied 56 internal iliac arteries 9 different branches were evaluated. The superior gluteal artery detected in all studied arteries with a score of 2 in all of them and sensitivity 1. The inferior gluteal artery also detected in all IIA (Score 2 in all; overall sensitivity of 1). The internal pudendal detected in all IIA (Score 2 in 55, score 1 in 1; sensitivity 1). The obturator artery detected in all IIA (Score 2 in 52, score 1 in 4; sensitivity 1). The iliolumbar artery detected in all IIA (Score 2 in 53, score 1 in 3; sensitivity 1). The lateral sacral artery detected in 55 IIA (Score 2 in 49, score 1 in 6, score 0 in 1; sensitivity 0.98). The inferior vesical (prostatic) artery detected in 45 IIA (Score 2 in 26, score 1 in 19, score 0 in 11; sensitivity 0.80). The middle rectal artery detected in 21 IIA (Score 2 in 5, score 1 in 16, score 0 in 35; sensitivity 0.38). Lastly the superior vesical artery detected in 2 IIA with a score of 1 (sensitivity 0.04).

CONCLUSION

3D-CE-MRA is a helpful non invasive tool in detecting most of the branches of the internal iliac artery in males. It can detect up to 80% of the prostatic arteries before PAE.

CLINICAL RELEVANCE/APPLICATION

3D-CE-MRA is a reliable method for mapping the internal iliac artery prior to PAE which might help in reducing the procedure time.

PURPOSE

To characterize the incidence/pattern of LLLN involvement in HPV-associated OPC and correlation with outcomes after radiation therapy (RT).

METHOD AND MATERIALS

We reviewed diagnostic/planning images and clinical data of an IRB-approved cohort of HPV-associated OPC patients (pts) treated with definitive RT at our institution from 2004-13. Demographics and outcomes were retrieved from the medical records. LLLN+ were defined as any radiographically involved level IV or Vb nodes. AJCC 8th edition staging was used. Actuarial outcomes were calculated using Kaplan-Meier and compared by log-rank test. One-way analysis of variance was used to compare proportions.

RESULTS

In 796 pts, the incidence of LLLN+ was 12%, 13% in base of tongue and 10% in tonsil primaries, 10% in N1, 17% in N2, and 48% in N3. Median follow-up was 58 months (IQR: 42-77). Induction chemotherapy (IC) was used in 80% vs. 37% and concurrent in 78% vs. 65% for those with vs. without LLLN involvement, respectively. The proportion of LLLN+ patients receiving IC was 70%, 93%, and 100% for those with N1, N2, and N3 disease, respectively (p=.0034). Overall, LLLN+ was associated with worse 5-year rates for all disease control endpoints tested except freedom from distant metastasis (FDM) with a trend for OS. In patients with N1 disease, LLLN-involvement was associated with worse rates of FDM (87% vs. 94%, p=.0214); no significant differences were observed in N2 or N3 subgroups for any endpoint. In patients who received IC, LLLN+ was associated with worse 5-year local control (LC), regional control (RC), and relapse-free survival (RFS), differences ranging from 6-11% (p-value<0.004 for each). When stratified by IC and N-category, LLLN+ was associated with lower FDM rates in N1 (86% vs. 94%, p=.014) but not N2 or N3 disease.

CONCLUSION

Reflective of the patterns of care of those treated during this study time frame, most pts with LLLN+ received IC, which could have potentially offset any adverse correlation with subsequent distant failure. However, LLLN+ correlated with other disease control endpoints (LC, RC, and RFS), and thus could be considered a marker of regionally advanced disease in HPV-associated OPC, even for those with lower stage.

CLINICAL RELEVANCE/APPLICATION

LLLLN involvement was associated with poorer disease control outcomes, and a potential influence of IC on subsequent distant failure is hypothesized.

MSRO23-02 Automatic Gross Tumor Volume (GTV) Delineation for Nasopharyngeal Carcinoma (NPC) Radiotherapy on Multi-modal MRI: A Deep Learning Model Trained from 1000 Patient Dataset

Monday, Nov. 26 1:40PM - 1:50PM Room: E450A

lifu5@mail.sysu.edu.cn

PURPOSE

GTV delineation of NPC is a critical and time-consuming process during intensity modulated radiotherapy. We are developing an automatic deep learning GTV delineation approach for NPC radiotherapy on multi-model MRI.

METHOD AND MATERIALS

With IRB approval, we retrospectively collected 1012 patients who underwent intensity modulated radiotherapy for NPC from Sept. 2016 to Aug. 2017. Multi-model MRIs (T1, T1C, T1W, T2) were acquired for GTV delineation of each patient with Philips MR imaging system and covered large variations in scanning parameters. Three experienced radiotherapists manually marked the GTV contours on MRI series (1 to 2 hours per case). In this study, a modified 3D U-net deep learning network was trained to perform volume-to-volume delineation of GTV. Multi-modal MRIs were regard as different channel input of the 3D U-net and feature maps from various layers were concatenated with deep supervision to generate the output as the corresponding GTV likelihood map. Binary cross-entropy was applied as loss function for network training. To increase receptive fields and capture contextual information, two-stride convolution was used to downsample feature maps instead of maxpooling operator. Besides, clinical anatomy characteristics were explored as post-processing to protect normal tissues and further improve the model performance. We randomly split the entire data set into training (850 cases) and independent testing (162 cases). Dice coefficient (DC), average percent volume error (AVE) and average absolute volume error (AAVE) were used to compare the computed GTV results with the experts' manual results.

RESULTS

The average DC, AVE and AAVE on test data are 0.79±0.05, -0.09±0.21, and 0.19±0.13, respectively. Comparing to 1-2 hours by the readers, our deep learning delineation takes less than 15 seconds per case.

CONCLUSION

Our results demonstrated the feasibility of deep learning approach for automatic GTV delineation of NPC during intensity modulated radiotherapy. Our automatic tool achieves good delineation quality on NPC GTV and greatly reduces the delineation time by hundred times compared to clinical doctors.

CLINICAL RELEVANCE/APPLICATION

Radiotherapy is one of the efficient routine treatment for NPC and accurate delineation of GTV is a key step in radiotherapy. Our automatic tool has potential to reduce the variability between human readers as well as improve the efficiency of the whole procedure.

MSRO23-03 Using Artificial Intelligence to Predict Oropharyngeal Cancer Recurrence After Radiation Therapy

Monday, Nov. 26 1:50PM - 2:00PM Room: E450A

richard.bakst@mountsinai.org

PURPOSE

HPV derived oropharyngeal cancers are less aggressive and more radiosensitive compared to non-HPV derived oropharyngeal cancers. In the HPV era, treatment de-escalation is one of the main areas of focus for clinical trials. However, recurrences still occur in HPV derived disease and can follow unique patterns, so it is important to identify patients at high risk of recurrence and ensure that they do not receive de-intensified treatment. Artificial intelligence can be used to analyze radiomic signatures and potentially predict recurrence. This would allow for personalized treatment planning based on radiographic risk profiles. Our purpose was to demonstrate that deep learning models have the potential to assess radiographic risk factors for oropharyngeal cancer recurrence.

METHOD AND MATERIALS

Radiotherapy planning CT scans of 108 patients with histologically proven oropharyngeal cancer were acquired from the TCIA Head-Neck-PET-CT collection. In this collection, all patients with recurrent cancer or metastases at presentation were excluded. Of 108 cases, 44 had loco-regional or distant recurrence of cancer after definitive radiation treatment. For each patient, a volume of interest (VOI) that embraces the Gross Tumor Volume was extracted from the entire CT scan. After being preprocessed for dimension standardization and intensity normalization, the VOI was input into a VGG16 based neural network to obtain a discriminative score, which indicates an estimate of the probability of recurrence of that tumor. Receiver Operating Characteristic (ROC) analysis was used to evaluate the classification performance of the VGG-based model.

RESULTS

By using 4-fold cross validation, the VGG-based classification model achieved an average accuracy of 0.59 and AUC of 0.60.

CONCLUSION

Our study shows that deep learning models have potential in predicting oropharyngeal cancer recurrence. This can eventually pave the way towards individualized radiation dosage planning based on radiomic signatures. A larger, multi-institutional dataset is required to further validate the model for clinical application.

CLINICAL RELEVANCE/APPLICATION

Artificial intelligence can be used to analyze radiographic features on CT simulation scans to predict recurrence risk and tailor radiation dosages in the HPV era of oropharyngeal cancers.

MSRO23-04 A Phase II, Proof-of-Concept Clinical Study of an Oral Mouth Rinse Containing Sandalwood Oil (SAO) for the Prevention of Oral and Oropharyngeal Mucositis Associated with (Chemo-) Radiation Therapy in Head and Neck Cancer Patients

Monday, Nov. 26 2:00PM - 2:10PM Room: E450A

Participants
Chul S. Ha, MD, San Antonio, TX (*Presenter*) Investigator, Santalis Pharmaceuticals, Inc
Ying Li, MD, San Antonio, TX (*Abstract Co-Author*) Investigator, Santalis Pharmaceuticals, Inc
Carol Jenkins, RN,MS, San Antonio, TX (*Abstract Co-Author*) Nothing to Disclose
Corey Levenson, PhD, San Antonio, TX (*Abstract Co-Author*) Officer, Santalis Pharmaceuticals

PURPOSE

Mucositis is one of the most debilitating side effects in patients treated with (chemo-) radiation therapy for head and neck cancer. This study was intended to evaluate the efficacy in alleviating mucositis, safety and tolerability of SAO (0.25% aqueous solution of an anti-inflammatory and anti-microbial essential oil from Santalum album trees).

METHOD AND MATERIALS

Patients to be treated with (chemo-) radiation therapy (>= 60 Gy) for cancers of oral cavity/oropharynx were asked to swish and gargle for 30 seconds, and spit, with 15 ml of the SAO three times a day throughout the radiation therapy. Pain in the oral cavity/oropharynx was measured using the numerical rating pain scale (NRPS) and mucositis was graded using the RTOG scale every week. Our data were compared with historical data in table 2 (incidence of mucositis), figure 1 (mean mucositis grade) and figure 2 (mean oral pain grade) from MD Anderson Cancer Center (MDACC) (doi:10.1016/j.ijrobp.2007.01.053) and table 4 (incidence of mucositis) from Memorial Sloan Kettering Cancer Center (MSKCC) (doi:10.1016/j.ijrobp.2010.10.041).

RESULTS

Fourteen subjects were enrolled but 6 withdrew (4 of them due to taste/smell of the rinse, 1 due to fatigue, 1 due to perceived ineffectiveness of the rinse). Among the 8 who completed the course of SAO treatment, 6 were treated with chemo-radiation and 2 with radiation only. IMRT was used for everyone. The median dose was 6,996 cGy in 33 fractions. There were no serious adverse events from SAO. The mean RTOG mucositis grades from weeks 3,6 and 9 were 1.125, 2.125 and 1.875. Two of 8 patients experienced mucositis >= 3. The corresponding mean NRPS were 3.700, 4.988 and 3.875.

CONCLUSION

The incidence of mucositis >= 3 were 70% from MDACC and 22% from MSKCC. Distribution of our mean NRPS and RTOG mucositis data compared favorably against figures 1 and 2 from MDACC. Though SAO was difficult to use due to poor taste/smell, it was otherwise well tolerated and appears to have enough signal to warrant further development as a potential alleviator of mucositis.

CLINICAL RELEVANCE/APPLICATION

This is a proof-of-concept clinical trial for an oral mouth rinse containing Sandalwood Oil for the prevention of mucositis associated with (chemo-) radiation therapy in head and neck cancer patients. We believe our results have generated enough signal to pursue further development of this preparation.

MSRO23-05 Locoregional Patterns of Failure (POF) following Therapeutic Dose Neck Radiation Therapy (RT) for Un-Resected Anaplastic Thyroid Cancer (ATC)

PURPOSE

Despite aggressive therapy, patients (pts) with ATC often develop locoregional progression (LRP). We aimed to identify the pattern of LRP in pts with un-resected ATC who received therapeutic doses of neck RT (>45 Gy).

METHOD AND MATERIALS

An institutional ATC database was retrospectively reviewed for pts who received neck RT from 01/00-08/17. ATC pts with un-resected disease were eligible if they received RT > 45 Gy at our institution and had follow-up CTs to assess for LRP. Progressive gross tumor volumes (rGTVs) were segmented on diagnostic CTs that demonstrated LRP (rCTs) and were reviewed by a head and neck radiation oncologist. rCTs were co-registered with treatment planning CTs (pCTs) using deformable image registration (VelocityAI 3.0.1). rGTVs were compared to original RT plans using a centroid-based approach. Failures were classified into 5 types based on pre-defined spatial/dosimetric criteria; A (central high dose), B (central elective dose), C (peripheral high dose), D (peripheral elective dose), and E (extraneous dose).

RESULTS

129 ATC pts received neck RT; of these, 103 had available plans and only 73 had plans and follow-up CTs. Of the 73, pts were excluded for prior resection (n=37) or if RT dose was $\leq$ 45 Gy (n=17). Thus, 19 formed the cohort. Most (79%) were Caucasian; median age was 63.5 years; 58% were stage IVC; 95% received IMRT; and all received systemic therapy. Median RT dose was 66 Gy (IQR: 59-66); median dose per fraction was 2 Gy (IQR: 1.7-2.2). Median follow-up was 7.9 mos. Six pts (31.5%) developed LRP and 16 rGTVs were identified (6 in 1 pt, 4 in 1, 3 in 1, and 1 in 3 each). Median time to LRP was 2.3 mos (range: 0-43). Of rGTVs, 7 were local (thyroid bed) and 9 were regional (1 in the paratracheal region; 1 in base of tongue [BOT]; 3 in node levels IIa; 1 in III; 2 in IV; and 1 in paraspinal musculature [PSM]). Type A was the most common rGTV POF (56%), followed by Types E (31%; 3 nodal, 1 BOT, and 1 PSM), B and C (8% each). Actuarial locoregional control (LRC) was 73% at 6 and 12 mos. Four living patients without LRP had a median follow-up of 27.5 mos (range: 9.3-65).

CONCLUSION

The identified POF was largely Type A and rapid (<6 mos), suggestive of a radiation resistance profile.

CLINICAL RELEVANCE/APPLICATION

Rapid neck progression was avoided in most ATC pts and some exhibited durable neck control, which could allow pts to receive subsequent systemic or targeted therapies.

MSRO23-06 A Population-Based Study of the Effects of Therapy, Primary Tumor Characteristics, and Metastatic Disease Sites on Survival in Patients with Metastatic Head and Neck Cancer

Monday, Nov. 26 2:20PM - 2:30PM Room: E450A

Awards
Student Travel Stipend Award

Participants
Justin Budnik, MD, Rochester, NY (*Presenter*) Nothing to Disclose
Nicholas J. Denunzio, MD, PhD, Boston, MA (*Abstract Co-Author*) Nothing to Disclose
Michael T. Milano, MD, PhD, Chicago, IL (*Abstract Co-Author*) Nothing to Disclose
Deepinder Singh, MD, Rochester, NY (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Data is emerging that multimodality therapy (MMT) may improve overall survival (OS) in patients with metastatic head and neck cancer (M1-HNC). We aim to investigate the effects of MMT, tumor characteristics, and sites of metastatic disease on OS in M1-HNC patients using the Surveillance, Epidemiology, and End Results (SEER) database.

METHOD AND MATERIALS

2,827 patients from the SEER 18 registry diagnosed with M1-HNC from 2010-2014 were analyzed. Patients coded as having metastatic disease in bone, brain, liver, and lung were identified. Kaplan-Meier analyses and Cox proportional hazards models were used to assess the impact of MMT, primary tumor characteristics, and metastatic disease sites on OS.

RESULTS

Most patients were male (n=2,169, 76.7%), and had squamous carcinoma histology (n=2,009, 71.1%). Median age was 60 years and median OS was 10 months. Oropharynx (n=900, 31.8%) was the most common primary site. Patients coded as having metastases in lung and not in bone, brain, or liver (n=958, 33.9%) were the most common metastatic disease category. 518 patients (18.3%) received cancer-directed surgery (CDS), 1,458 patients (51.6%) received radiation (RT), and 1,690 patients (59.8%) received chemotherapy (CT). 579 patients (20.5%) received neither CDS, nor RT, nor CT (no therapy-group). With Cox regression accounting for age, sex, race, primary site, histology, grade, T stage, N stage, and metastatic sites, those who received CDS, RT, and CT (n=172, 6.1%) had the largest OS benefit (HR=0.22, 95% CI 0.17-0.28, p<0.001) compared to the no therapy-group. Patients receiving RT and CT were the most common MMT combination (n=879, 31.1%), and had improved OS (HR=0.35,

95% CI 0.30-0.40, p<0.001) compared to the no therapy-group. Primary and metastatic disease site-specific analyses showed that MMT combinations provided and OS benefit at all primary sites in the head and neck region and across metastatic sites with the exception of those coded as having metastases in bone and lung, and not in brain and liver.

CONCLUSION

In this hypothesis-generating study MMT is associated with improved OS in patients with M1-HNC. The OS benefit persists across primary and metastatic disease sites. Prospective study of MMT in M1-HNC patients is warranted.

CLINICAL RELEVANCE/APPLICATION

In this population-based, hypothesis-generating study multimodality therapy is associated with improved overall survival in patients with metastatic head and neck cancer.

MSRO27-03 Where Are the RCTs? Analysis of the 2018 American Society for Radiation Oncology (ASTRO) Evidence-Based Guidelines for Radiation Therapy to the Whole Breast as Treatment for Breast Cancer

Monday, Nov. 26 1:50PM - 2:00PM Room: S103CD

Participants
Norman R. Williams, PhD, London, United Kingdom (*Presenter*) Travel support, Carl Zeiss AG

For information about this presentation, contact:

norman.williams@ucl.ac.uk

PURPOSE

Early in 2018, the American Society for Radiation Oncology (ASTRO) produced evidence-based guidelines on five key questions for radiation therapy to the whole breast as treatment for breast cancer [Smith et al PMID: 29545124]. An analysis was made of the publications supporting these guidelines to determine how many reported level-1 evidence from randomised clinical trials (RCTs), as this is the standard applied to chemotherapy and adjuvant hormonal therapy.

METHOD AND MATERIALS

All 112 references were scrutinized, and tabulated according to level of evidence (RCT or not), year of publication, country of lead author, and which of the statements (grouped into five key questions) they addressed.

RESULTS

Of the 33 statements, 12 are not supported by evidence from RCTs. In a further 9 statements, data from RCTs only partly support the consensus. Therefore, 21/33 (64%) of the statements are not directly supported by evidence from RCTs. There is no evidence from RCTs to support any of the statements regarding avoiding exposure of cardiac and other normal tissue (key questions 4 and 5). Such exposure has been linked to death from ischemic heart disease [Darby et al PMID: 23484825] and lung cancer [Taylor et al PMID: 28319436]. There is evidence that the effects of a course of whole breast radiation therapy induces early ECG changes [Tuohinen et al PMID: 29599341]; biological effects can be detected after a single fraction [Woolf et al PMID: 25045612]. Such measures could be used in the design of RCTs, particularly of patients with low-risk breast cancer in whom de-escalation of breast radiation therapy (using accelerated partial breast, intra-operative, etc.) may be warranted to reduce an imbalance in the efficacy/safety profile [Franco et al PMID: 29616366].

CONCLUSION

The majority of the 2018 ASTRO evidence-based guidelines for use of radiation therapy in breast cancer are not based on level-1 evidence from RCTs. Trials using techniques that minimize exposure to normal tissues are urgently required.

CLINICAL RELEVANCE/APPLICATION

Clinicians and patients should be aware that current guidelines for treatment of breast cancer using radiation therapy are mostly based on sub-optimal evidence.

MSRO27-04 Clinical Outcomes and Toxicity of Proton Beam Radiation Therapy for Re-Irradiation of Locally Recurrent Breast Cancer

pgabani@wustl.edu

PURPOSE

Repeat radiation therapy (RT) using x-rays for locally recurrent breast cancer results in increased short and long-term toxicity. Proton beam RT (PBRT) can minimize dose to surrounding organs thereby reducing toxicity. Here, we report the toxicity and outcomes for women who underwent re-irradiation to the chest wall for locally recurrent breast cancer using PBRT.

METHOD AND MATERIALS

A total of 16 patients with locally recurrent breast cancer who underwent re-irradiation to the chest wall with PBRT between 2014-2018 were retrospectively analyzed. For their recurrences, 6 patients underwent salvage mastectomy, 8 patients had wide local excision, and 2 patients had biopsy only. The median dose for the first RT course was 50 Gy, and for the second course, 50.4 Cobalt Gy Equivalent. The target for re-irradiation was chest wall alone in 12 patients and chest wall plus regional nodes in 4 patients. A boost was delivered in 3 (18.8%) patients. Concurrent hyperthermia was used in 10 (62.5%) patients. For systemic therapy, 4 (25%) patients received chemotherapy and 8 (50%) patients received hormone therapy. Follow up was calculated from the start of second RT course. Toxicities were based on CTCAE 4.0.

RESULTS

The median age at diagnosis and at recurrence was 49.8 years and 60.2 years respectively. The median time between the two RT courses was 10.2 (0.7-20.2) years. The median follow up time was 10.6 (1.5-29.1) months. There were no local failures observed after re-irradiation. Only one patient developed distant metastasis and ultimately died. Grade 3-4 acute skin toxicity was observed in 5 (31.2%) patients. There were 4 (25%) patients who developed chest wall infections during or shortly (2 weeks) after re-irradiation. Grade 3-4 fibrosis was observed in only 3 (18.8%) patients. Grade 5 toxicities were not observed. Hyperpigmentation was seen in 12 (75%) patients. Other RT related toxicities such as pneumonitis, telangiectasia, rib fracture, and lymphedema occurred in 2 (12.5%), 4 (25%), 1 (6.3%), and 1 (6.3%) patients respectively.

CONCLUSION

Re-irradiation with PBRT for recurrent breast cancer has acceptable toxicities. There was a high incidence of grade 3-4 skin toxicity and infections, however, they resolved with skin care and antibiotics. Further follow up is needed to determine long-term clinical outcomes.

CLINICAL RELEVANCE/APPLICATION

PBRT can be safely used for re-irradiation of the chest wall for locally recurrent breast cancer.

MSRO27-05 Carcinosarcoma of the Breast: Treatment Patterns and Survival Outcomes

Monday, Nov. 26 2:10PM - 2:20PM Room: S103CD

Awards
Trainee Research Prize - Resident

Imran Zoberi, MD, St. Louis, MO (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Carcinosarcoma of the breast is a rare yet highly-aggressive tumor accounting for less than 1% of all breast cancers, for which guidance on optimal management and prognosis are sparse. The purpose of this study is to investigate population-based treatment patterns and overall survival (OS) outcomes in patients with this diagnosis.

METHOD AND MATERIALS

We queried the National Cancer Database for patients diagnosed with carcinosarcoma (Histology 8980) of the breast. All patients included were treated with surgery, with or without chemotherapy and/or radiation therapy. Patients with metastatic disease were excluded. Kaplan-Meier analysis was used to estimate OS. Univariate and multivariate cox analyses were used to determine predictive factors of OS.

RESULTS

A total of 329 patients from 2004-2012 were identified. Median age at diagnosis was 58 years (range, 24-90). Patients had T1 (21%), T2 (44%), T3 (25%), or T4 disease (10%). Most patients were node-negative at diagnosis (77%). Breast conservation surgery was utilized in 33% of patients. Chemotherapy was used in 66% of patients. Less than half (44%) of patients received radiation therapy to a median dose of 50.4Gy (range 35-56 Gy), with a median 10Gy boost used in 76%. With median follow-up of 39.9 months, 3-year overall survival was 74%. Multivariate analysis revealed that T-stage, margin status, and chemotherapy use all significantly influenced OS. There was a trend towards improved survival with the use of RT (HR 0.66, 95% CI 0.43-1.01, p =0.053). The 3-yr OS was 80% in patients receiving chemotherapy vs 59% without chemotherapy. The 3-yr OS was 82% in patients receiving RT vs 66% without RT.

CONCLUSION

Carcinosarcoma of the breast is associated with relatively poor rates of OS. The use of chemotherapy was associated with improved OS, with a trend towards improved OS with the use of RT.

CLINICAL RELEVANCE/APPLICATION

In the largest study to date investigating outcomes in carcinosarcoma of the breast, adding chemotherapy to surgery improved OS. A trend toward improved OS was also seen with adjuvant RT.

MSRO27-06 Quantitative Ultrasound Characterization of Radiation-Induced Acute Skin Toxicity in Breast Cancer Patients Receiving Radiation Therapy: A Feasibility Study

Monday, Nov. 26 2:20PM - 2:30PM Room: S103CD

Participants
Sylvia D. Tang, Johns Creek, GA (*Presenter*) Nothing to Disclose
Jiwoong Jason Jeong, Atlanta, GA (*Abstract Co-Author*) Nothing to Disclose
Xiaofeng Yang, PhD, Atlanta, GA (*Abstract Co-Author*) Nothing to Disclose

Tian Liu, PhD, Atlanta, GA (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Despite technological advances in radiotherapy, high dose of radiation may induce acute skin toxicity in the majority of women receiving breast-cancer radiotherapy. In current clinical practice, the severity of skin toxicity is often rated by clinicians through visual inspection and physics examination, which is subjective. The purpose of this study is to investigate the feasibility of quantitative characterization of radiation-induced acute skin toxicity via ultrasound morphological and texture analysis.

METHOD AND MATERIALS

Twelve patients receiving standard breast radiotherapy were enrolled in the longitudinal ultrasound study. Ultrasound B-mode images are acquired at various time points: prior to, weekly during, as well as 6 weeks and 3 months post radiotherapy. At each time point, 4 images (12, 3, 6 and 9 o'clock) were acquired on the irradiated breast and 4 mirror images were acquitted on the contralateral normal breast. To evaluate radiation-induced skin changes, we performed both morphological (area, height, perimeter and averaged skin thickness) and textural (contrast, angular second moment (ASM) and inverse difference moment (IDM)) analyses using ImageJ. Clinical assessment of skin toxicity was performed at each time point.

RESULTS

Changes in skin thickness and texture were observed in 5 patients as early as 1 week during treatment. In 2 cases with most severe acute toxicity, the average skin thickness of irradiated breast increases more than 175% and 188% at the end of fractionated therapy in comparison to the untreated contralateral breast, while their slopes in linear regression are 0.87 and 0.70, respectively. Acute skin toxicity was observed in differences in 5 cases in the angular second moment measurements and in 4 cases of entropy analysis over the patient's temporal treatment course.

CONCLUSION

Radiation-induced skin toxicity in breast cancer patients can be quantitatively assessed by ultrasound-based morphologic and textural characterization.

CLINICAL RELEVANCE/APPLICATION

Quantitative ultrasound characterization of radiation-induced acute skin toxicity in breast cancer patients receiving radiation therapy may be of clinical relevance for the optimization of treatment protocols and potential early intervention to prevent long-term breast toxicity.

PURPOSE

Radiomic information of segmented tumors in breast images have been shown to be correlated with prediction of certain markers/surrogates for prognosis. Surrounding regions of tumor may have been affected by tumor development but its effects remain unclear for similar prediction purposes. We performed an investigation on the radiomic imaging features extracted from both tumor and surrounding regions in relation to prediction of breast cancer distant recurrence risk and tumor proliferation markers.

METHOD AND MATERIALS

We performed an IRB-approved retrospective study on 119 ER-positive and node-negative invasive breast cancer patients diagnosed (confirmed by pathology) during 2011-2016. All patients had FFDM scans (including MLO and CC views), Oncotype DX recurrence risk scores, and proliferation markers (Ki-67) available. Breast tumor was segmented by an expert breast imaging radiologist, and a varying size (diameter) of surrounding regions outside the segmented tumor were automatically separated using automated image processing techniques. A total of 23 radiomic features were extracted respectively from tumor and its surrounding region. The logistic least absolute shrinkage and selection operator (LASSO) regression model was used to estimate the Oncotype DX risk score and Ki-67 rate, respectively, using the same set of 23 features. AUC and Pearson's correlation coefficient (r) are performance metrics.

RESULTS

For features extracted from tumor alone, r was 27% ($p < 0.05$) and 35% ($p<0.05$) for estimating Oncotype DX and Ki67, respectively, while the corresponding AUC was 0.77 (High Oncotype DX vs Intermediate and low) and 0.58 (High Ki-67 vs low Ki-67). When imaging features from the surrounding regions (6 mm outer from tumor boundary) were incorporated additionally, r increased to 34% ($p<0.05$) and 47% ($p<0.05$) for estimating Oncotype DX and Ki-67, respectively, while the AUC was 0.78 and 0.63. The LASSO-selected features included the tumor solidity, surrounding region's skewness and intensity contrast.

CONCLUSION

Inclusion of the surrounding regions of breast tumor in FFDM increased the performance of predicting Oncotype DX recurrence risk scores and Ki-67 proliferation rate.

CLINICAL RELEVANCE/APPLICATION

Surrounding regions of breast tumor in FFDM may provide additional quantitative information over tumors to enhance prognosis and proliferation estimation

sohn87@gmail.com

PURPOSE

The current edition of BI-RADS assigns breast density qualitatively based on potential for obscuring breast cancer, rather than a simple quantitative summation of image intensities. The aim of this study is to develop a deep learning algorithm for breast density classification based on the new BI-RADS system and then retrospectively apply them to a separate set of digital mammograms to automatically classify breast density according to BI-RADS 5th Edition.

METHOD AND MATERIALS

A convolutional neural network with ResNet50 architecture was trained on 94,562 screening mammograms performed from 2014 to 2018 from a single institution following the current 5th edition of BI-RADS for mammography. Optimal neural network hyperparameters were selected via validation accuracy monitoring. The trained model was then applied to a hold-out test set of size 9,547 from the same institution. We then manually inspected all 13 cases in which the predicted label differed by more than 2 density labels from the ground truth. This algorithm was applied to 433,760 screening mammograms in large scale.

RESULTS

Our deep learning model achieved high sensitivity and specificity in assigning breast density category. Breast density distribution for the training data was 7,752 (A: 8.20%), 35,656 (B: 37.71%), 40,943 (C: 43.30%), and 10,211 (D: 10.79%). The AUCs of ROC curves on the test set were 0.97, 0.93, 0.92, and 0.96, respectively for each breast density category. Error analysis revealed that among the 13 cases where breast density differed by more than 2 classes between actual and predicted labels, 7 were due to breast implants, 4 were due to incorrect ground truth labels, and 2 remained equivocal. After the model was applied to the 433,760 screening mammograms, the model-predicted breast density distribution came to be 40,109 (A, 9.25%), 151,893 (B, 35.02%), 193,283 (C, 44.56%), and 48,475 (D, 11.17%).

CONCLUSION

Our deep learning algorithm successfully modeled the breast density classification scheme in the 5th edition BI-RADS system. This was retrospectively applied in large scale to 433,760 mammograms for further inspection.

CLINICAL RELEVANCE/APPLICATION

Qualitative breast density assessment by radiologists is subject to variability. Given widespread adoption of breast density notification laws in the U.S., automated breast density assessment based on masking can improve consistency of breast density assignment particularly between categories B & C.

SSE01-03 Using Quantitative Breast Density Analysis to Predict Interval Cancers and Node Positive Cancers in Pursuit of Improved Screening Protocols

Monday, Nov. 26 3:20PM - 3:30PM Room: E451B

Participants
Elizabeth S. Burnside, MD,MPH, Madison, WI (*Presenter*) Dr. Burnside has a research grant from Hologic
Lucy M. Warren, PhD, Guildford, United Kingdom (*Abstract Co-Author*) Nothing to Disclose
Louise S. Wilkinson, MBBCh,FRCR, London, United Kingdom (*Abstract Co-Author*) Nothing to Disclose

Jonathan Myles, London, United Kingdom (*Abstract Co-Author*) Nothing to Disclose
Stephen W. Duffy, London, United Kingdom (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

This study investigates whether quantitative breast density can predict interval cancers and node positive screen detected cancers in order to serve as a biomarker to consider more aggressive screening to improve early detection.

METHOD AND MATERIALS

We conducted a case-control study of 1204 women drawn from the U.K. NHS Breast Screening Program aged 50-74 including 599 cases (comprising 302 screen detected cancers, 297 interval cancers; 239 node positive, 360 node negative) and 605 controls. Each woman had prior digital mammograms and 70% had unprocessed images. A radiologist assessed breast density using a visual analog scale (VAS) from 0 to 100 and BI-RADS 5th Edition density categories. Volpara software (V1.5.1) calculated fibroglandular volume (FGV) and volumetric density grade (VDG) on unprocessed images. Logistic regression determined whether the breast density measures could predict mode of detection (screen detected or interval); node-negative cancers; and node-positive cancers, all vs. controls.

RESULTS

FGV predicted both screen-detected ($p<0.01$) and interval cancers ($p<0.01$) compared to controls. VDG, VAS and BI-RADS

FGV predicted both screen-detected (p<0.01) and interval cancers (p<0.01) compared to controls. VDG, VAS and BI-RADS predicted interval cancers (all p<0.01) but not screen-detected cancers (p=0.16, p=0.18, p=0.46 resp.). FGV demonstrated impressive risk stratification with an age-adjusted relative risk (RR) of the 4th quartile compared to the 1st quartile of 3.7 overall, 2.8 for screen detected, and 5.3 for interval cancers. VDG also had notable risk stratification with an age-adjusted RR of 3.6 for interval cancers (Table). FGV predicted node-negative cancers as compared to controls (p<0.01) while BI-RADS, VAS, and VDG did not (p=0.07, p=0.09, and p=0.47 resp.). FGV, BI-RADS, and VDG predicted node-positive cancers (all p<0.01) while VAS did not (p=0.14).

CONCLUSION

FGV predicts interval, screen detected, node-positive and node-negative cancers compared to controls and provides remarkable stratification the RR of interval cancers. BI-RADS and VDG predict interval and node positive cancers. VAS only predicts interval cancers. The quantitative and automated nature of FGV and VDG and notable risk stratification based on RR indicates that these variables may be promising biomarkers.

CLINICAL RELEVANCE/APPLICATION

By predicting mode of detection and nodal status, FGV may be a biomarker for more intensive screening. By predicting interval cancers, BI-RADS, VAS, and VDG may act as supplementary biomarkers.

SSE01-04 Fully-Automated Volumetric Breast Density Estimation from Digital Breast Tomosynthesis: A Case-Control Comparison to Area-Based Density Measures from Digital Mammography

Monday, Nov. 26 3:30PM - 3:40PM Room: E451B

Participants
Aimilia Gastounioti, Philadelphia, PA (*Presenter*) Nothing to Disclose
Meng-Kang Hsieh, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose
Lauren Pantalone, BS, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose
Emily F. Conant, MD, Philadelphia, PA (*Abstract Co-Author*) Grant, Hologic, Inc; Consultant, Hologic, Inc; Grant, iCAD, Inc; Consultant, iCAD, Inc; Speaker, iiCME
Despina Kontos, PhD, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To investigate associations between breast cancer and fully-automated volumetric density measures extracted with digital breast tomosynthesis (DBT), while also comparing to area-based density measures from digital mammography (DM).

METHOD AND MATERIALS

We retrospectively analyzed contralateral combo DM-DBT studies (Selenia Dimensions, Hologic Inc.) from 174 women with unilateral breast cancer and 696 controls matched to cases on age, ethnicity and screening exam date at a 4:1 ratio. The publicly available 'LIBRA' software (v1.0.4) was adapted and used to estimate absolute dense volume (DV) and volumetric percent density (VPD) from DBT, and absolute dense area (DA) and area percent density (APD) from DM images. Quantra (v2.2; Hologic Inc.) was also applied to DM images, allowing to evaluate APD as well as to infer DV and VPD via physics-based models. Associations between the different density measures and breast cancer were evaluated via logistic regression after adjustment for age, ethnicity and body mass index (BMI). Area under the curve (AUC) of the receiver operating characteristic was used to assess case-control discriminatory capacity, where model performance was compared using the DeLong's test, and odds ratios (ORs) for each of the density measures were estimated.

RESULTS

All density measures had a significant association with breast cancer (OR = 1.24-2.40) after adjustment for age, ethnicity and BMI. Models based on volumetric density measures had significantly ($p < 0.05$) larger case-control discriminatory capacity (AUC = 0.59-0.63) than models considering area density (AUC = 0.57-0.59). Maximum breast cancer association was observed for DV with slightly ($p = 0.440$) improved performance when extracted with DBT (AUC = 0.63) relative to DV inferred from DM (AUC = 0.61).

CONCLUSION

Fully-automated, quantitative, volumetric evaluation of breast density from DBT is feasible and can result in larger case-control discriminatory capacity than area-based density measures from conventional planar mammography. Associations with breast cancer can potentially further improve when volumetric density evaluation is performed with the DBT reconstructed breast volume compared to physics-based models applied to DM.

CLINICAL RELEVANCE/APPLICATION

Our results further elaborate important clinical implications of breast density measures estimated with DBT, which may result in improved measures of breast density in breast cancer risk assessment.

SSE01-05 Predicting Masking Risk in Mammography

james.mainprize@sri.utoronto.ca

PURPOSE

Masking in mammography is the reduction of lesion conspicuity by surrounding and overlying dense tissue. Masking risk is increased in dense breasts, leading to reduced sensitivity of breast screening. We have developed a masking index that can predict the likelihood of a masked or missed cancer and could be used in a screening program to stratify women at greatest risk of masking to alternative or supplementary imaging modalities to mammography.

METHOD AND MATERIALS

The study population were cancer cases collected (2003-2013) a case-control study used to develop a breast cancer risk model incorporating density measures. Cancers were classified as screen-detected cancers (SDC) found on a screening mammogram and non-screen detected cancers (NSDC) found by clinical symptoms or other imaging. The study had ethics board approval with informed consent All SDC found on baseline images were excluded. Inclusion as NSDC required at least one prior negative screening exam within two years of diagnosis. Images were analyzed with in-house algorithms and by volumetric breast density (VBD) software. The aim in this study was to create an index that differentiated mammograms which allowed for detection (SDC) from those for causing masking or missed lesions (NSDC). To avoid the influence of the lesion itself, only the contra-lateral breast images were used.

RESULTS

The study included 90 NSDC cases and 186 SDC controls. Univariate masking indices based on BMI, age, BI-RADS density, VBD or mean detectability yielded areas under ROC (AUC) of 0.61, 0.65, 0.67, 0.72 and 0.75 (±0.06 95% confidence) respectively. For cancers found within one year, the detectability AUC improved to 0.81.

CONCLUSION

Age and BMI are relatively weak predictors of masking risk whereas VBD and detectability measures have better performance. Further, adding textural measures improve predictions slightly, suggesting that the masking effects of anatomic noise and texture are informative. In future, we will validate the model in an independent population and test the result on normal mammograms to predict impact on a stratified screening program.

CLINICAL RELEVANCE/APPLICATION

A reliable masking index to predict when mammography will underperform would be a valuable tool in a stratified screening program which could be used to redirect women with highly masked mammograms to alternative or adjunct screening strategies such as tomosynthesis, MR or ultrasound.

SSE01-06 Quantitative MRI Background Parenchymal Enhancement and Contralateral Breast Cancer Risk

wus3@upmc.edu

PURPOSE

MRI background parenchymal enhancement (BPE) has been shown to be correlated with the risk of developing breast cancer in breast-cancer free women. History of breast cancer is a significant risk factor of contralateral breast cancer. We investigated the association between quantitative MRI BPE measures and risk of contralateral breast cancer development in a case-control setting

METHOD AND MATERIALS

A retrospective case-control (1:2 case-control ratio) study was performed using breast DCE-MRI scans from 135 newly diagnosed unilateral breast cancer patients (confirmed by pathology) from 2010-2016: 35 women had future contralateral breast cancer development after the initial breast cancer diagnosis and 70 were age- and year-of-MRI matched controls that remained breast cancer-free in the contralateral breasts after at least 1-year follow-up. The MRIs acquired at the initial diagnosis of the unilateral breast cancer were analyzed using published automated computer algorithms, generating two quantitative BPE measures computed from the first post-contrast series: the absolute BPE volume (|BPE|) and its relative amount over the whole breast volume (BPE%). Volumetric amounts of fibroglandular (dense) tissue (|FGT| and FGT%) were also automatically quantified from the MRI. Conditional logistic regression was performed to assess these BPE and FGT measures as predictors of the contralateral breast cancer development.

RESULTS

Average age was 52.2±13.1 (range 28-81) for cancers and 52.8±12.9 (range 28-80) for controls. 51% (or 49%) are post-menopause for cancers (or controls). Invasive other-cancer history was found in less than 10% of the patients for both cancer cases and controls. None of the |FGT|, FGT%, |BPE|, BPE% measures is statistically significant (all $p>0.05$) in terms of the difference between the cancer group and control group. Logistic regression showed that odds ratios of these four measures are very close to 1 with no statistical significance.

CONCLUSION

This pilot study showed that MRI BPE quantified in the contralateral breast of unilateral breast cancer patients is not associated with the future development of the contralateral breast cancers.

CLINICAL RELEVANCE/APPLICATION

BPE may be affected bilaterally even in unilateral breast cancer patients. Contralateral breast cancer risk markers can guide

treatment selection and risk reduction, meriting further investigation.

For information about this presentation, contact:

phamn@vcu.edu

PURPOSE

Expectations for when and how to receive results for mammograms are uncertain and the goal of this study is to explore expectations for patient care with regards to receiving mammogram results. The purpose of the study was to understand the majority preference with regards to the wait time for screening mammogram results, whether prompt communication of mammogram results was of importance to patients, whether the time frame to schedule an additional imaging follow-up appointment after an abnormal screening mammogram was of importance to patients, and how patients preferred to be given their screening mammogram results. From the survey, investigators wanted to determine whether any quality practice improvements are necessary at their academic breast imaging centers in order to improve the communication of screening mammogram results.

RESULTS

There were 2,245 patients who participated in the survey. A majority of patients preferred to receive results on Friday (N=1,868, 85.4%). Most individuals preferred to schedule their follow up appointments soon after their initial appointment, preferring either the next day or within 1-2 days. Finally, over half of the sample preferred to be contacted via a phone call, with letter and text messaging being the next most preferred methods. The preference for receiving results on Friday was evaluated by each of the patient characteristics. The responses by the patients for preference for receiving results on Friday were significantly different by ethnicity, education, and clinic. In particular, patients of other ethnicities besides African Americans and Caucasians responded with the highest percent to receiving results on Friday and Caucasians were the least inclined to prefer to receive results on Friday. Individuals with some college and college degrees were more likely to not prefer receiving results on Friday than those with no formal education or high school graduates. The preferred time for scheduling a follow up was assessed by each of the patient characteristics. Across all the patient characteristics, patients preferred to schedule their follow up appointment the next day. Lastly, first choice of contact was examined across each of the patient characteristics. Phone call was the overwhelming choice for method of contact for all patient characteristics.

CONCLUSION

The findings suggest that the patient population surveyed have a preference for their wait time, which is either to wait or receive them within 24 hours. Patients preferred to receive results on Friday, and the most frequent choice for scheduling a follow up appointment was the next day. A phone call was the preferred first choice for method of contact with e-mail being the least preferred. These suggestions can help clinics and providers make changes to how they communicate their results. These findings may help to streamline results for patients who prefer a shorter wait time, and highlight the overwhelming patient preference to receive their abnormal screening mammogram results on a Friday. The findings may also suggest how to contact patients in a different way, as phone calls were the preferred method of contact. The strong preference of patients receiving their screening mammogram results more promptly should help trigger alternative methods toward improving communication between the radiologist and the patient.

METHODS

Patients The study population was patients aged 18 or older, who completed an anonymous paper survey consisting of eight questions when coming in for a routine mammogram screening. The study period lasted from September to November 2017 at two academic breast-imaging centers. *Measures* The primary objective of the study was to summarize the results from a survey examining the communication of mammography results from the patient population. The association between patient demographics

and four outcomes, preferred wait time, preferred scheduling time for a follow-up appointment, preference for receiving screening results on Friday, and preferred methods of contact was investigated. Parameters of the survey are summarized in attached Table 1. *Statistical Methods* Frequencies and percentages for clinic site, age, ethnicity, education, and insurance were calculated. Pearson chi-square analyses were conducted to determine the association between wait time preference and each patient demographic, between preferred scheduling time for follow-up appointment and each patient demographic, between preference for receiving screening results on Friday and each patient demographic, and between the first choice of method of contact and each patient demographics. SAS version 9.4 was used for all analyses.

PURPOSE

Rural disparities in screening utilization are known to be affected by lack of access to care providers; city-level screening mammography disparity has been less well evaluated, although over 30 million adult women live in the 500 largest cities. Our purpose is therefore to evaluate disparities in screening in US cities.

METHOD AND MATERIALS

This descriptive study used public data from the 500 Cities project--500 largest cities, 103,020,808 individuals--which includes self-reported screening uptake (127,298 women ages 50-74) from the Behavioral Risk Factor Surveillance System (BRFSS). Uptake was matched with BRFSS and American Community Survey national population/economic census data variables expected to impact screening: geographic region, health insurance, median household income, obesity, race, combined preventive care services (flu, pneumococcal shots, colorectal screening), and pap smear use. Cities with incomplete data were excluded, yielding 490 cities, 34,629,163 women. Univariable and multivariable analyses were performed. All statistical tests were conducted at the two-sided 5% significance level using SAS 9.3 software (SAS Institute, Cary, NC).

RESULTS

Mean city screening mammography utilization was 77.7% (62.8%-88.9%). Utilization was highest in New England cities ($p<0.002$), significantly positively correlated with pap smear ($r=0.75$), other preventive services ($r=0.3$), household income ($r=0.44$), %Asian race ($r=0.36$), weakly with %Black race ($r=0.10$); significantly negatively correlated with obesity ($r=-0.36$), poverty ($r=-0.30$), %White race ($r=-0.29$), no insurance ($r=-0.27$), ($p<0.05$ for all); not significantly correlated with population size ($p=0.651$). Multivariable analysis demonstrated Pap smear use, Asian race, private insurance, and geographic region to be significant independent predictors of utilization.

CONCLUSION

Screening mammography utilization varies across large cities in the U.S. with highest uptake in New England. Although the literature focuses on rural screening disparities, disparities also exist even across large cities without physical barriers to screening.

CLINICAL RELEVANCE/APPLICATION

Mammographic screening disparities exist at the city level; identifying predictors of uptake may aid in targeting areas and populations for screening education and intervention.

SSE02-03 Aligning Insurance Benefit Design with Patient Preference for Out-of-Pocket Cost Payments

PURPOSE

Alternative payment models encourage physicians to accept payment bundles. Their patients continue to pay fee-for-service (FFS) out of pocket costs, contrary to their preference for predictable out of pocket costs for a care episode. Using a hypothetical screening mammography diagnostic episode of care, we assessed patient preference for FFS vs bundled copayments (copays).

METHOD AND MATERIALS

After IRB approval, we recruited a population-based cross-sectional survey of women 40-75 years old through Survey Sampling International. Participants read a hypothetical scenario describing a screening mammography episode of care where 12% of women undergoing screening needed a follow-up breast ultrasound and 2% a breast biopsy. Estimated out-of-pocket (OOP) costs for these services and the characteristics of OOP payment types (FFS and a hypothetical bundled copay) were also described. We assessed OOP payment type preference and knowledge (7 true/false items, see Fig. 1), additional test cost worry (7-point scale from not at all to very worried), likelihood of mammogram use by OOP payment type and willingness to pay (WTP) for a breast screening episode bundle.

RESULTS

Participant (n=1,236) characteristics are described in Fig. 1. 82.9%preferred bundled copays over FFS and 70.8% answered at least half of the knowledge questions correctly. While most participants (74.5%) indicated they would get screened regardless of OOP payment type, 13.8%said they would only get screened with bundled copays and 3.4% with FFS. Sizeable percentages of participants were worried about costs associated with the ultrasound (42.0%) and biopsy (67.7%). Median WTP was $81 (25-75IQ=$34-$215) for a bundle to avoid paying additional OOP for possible ultrasound or biopsy.

CONCLUSION

Given worry over the cost over potential additional tests, participants preferred a predictable OOP cost for a breast screening episode, despite the low likelihood of additional testing. Although most participants would not defer mammography based on OOP payment type, a significant minority were more likely to screen if bundled copays were available. Insurers should consider incorporating these preferences in future benefits.

CLINICAL RELEVANCE/APPLICATION

Designing insurance plans to include bundled copays may decrease financial barriers to breast cancer work-up and diagnosis after screening mammography.

cgiess@bwh.harvard.edu

PURPOSE

To evaluate patient, radiologist, and examination characteristics affecting individual screening mammography recall rates in a large academic breast imaging practice.

METHOD AND MATERIALS

This Institutional Review Board approved retrospective study included all screening mammography examinations in female patients interpreted by thirteen breast imaging specialists at an urban academic center and two outpatient imaging centers from 10/1/2012-5/31/2015. Patient demographics were extracted via electronic medical record. A natural language processing algorithm captured breast density, BI-RADS assessment, and current and prior screening examination findings. Radiologists' annual screening volumes, years of clinical experience, and percentage of time doing breast imaging were calculated. Risk aversion, stress from uncertainty, and malpractice concerns were derived via online survey. Univariate and multivariate analyses assessed patient, radiologist, and examination characteristics associated with likelihood of mammography recall. Pearson product-moment correlation coefficient assessed relationship between cancer detection rate and recall rate.

RESULTS

Overall, 5,678 (9.3%) of 61,198 screening examinations were recalled. In multi-variate analysis, patient and radiologist characteristics associated with higher odds of recall included patient's age < 50 years ($p<0.0001$); calcification ($p<0.0001$), mass ($p<0.0001$), and higher density category ($p<0.0001$) on prior mammogram; baseline examination ($p<0.0001$); annual reading volume < 1250 screening exams ($p=0.0282$); and <10 years experience ($p=0.0036$). Radiologist's risk aversion, stress from uncertainty, malpractice concerns, or cancer detection rates were not associated with higher recall rates ($r=-0.36$, $p=0.23$).

CONCLUSION

In addition to patient and examination factors, screening recall variations were explained by radiologist's annual reading volume and experience. Interventions targeting radiologist factors may reduce unwarranted variation in screening recall and improve patient's care experience.

CLINICAL RELEVANCE/APPLICATION

Efforts to reduce screening recall rate variability and false positive recalls might include increasing annual screening interpretive volumes and review of uncertain screening findings for less experienced radiologists by more experienced breast imaging specialists.

SSE02-05 Preventive Care: How Comorbidities Affect Mammography Screening Rates

Monday, Nov. 26 3:40PM - 3:50PM Room: E450B

Awards
Student Travel Stipend Award

Participants
Cindy Yuan, MD,PhD, Chicago, IL (*Presenter*) Nothing to Disclose
Kirti M. Kulkarni, MD, Chicago, IL (*Abstract Co-Author*) Nothing to Disclose
Brittany Z. Dashevsky, MD,DPhil, Chicago, IL (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Here we evaluate the impact of comorbid conditions and age on screening mammography utilization.

METHOD AND MATERIALS

Data was retrospectively drawn from the 2011-2015 Medical Expenditure Panel Survey, which contained 40,752 women over the age of 40. Utilization was defined as a screening mammogram within the previous one or two years, analyzed separately. A logit model was employed to evaluate correlation of comorbidities with utilization. Statistical significance was defined by a p-value <0.05 by two-sided test.

RESULTS

Of the 36,575 women in the final sample, 45.9%, 43.6%, 3.9%, and 5.7% reported a history of hypertension (HTN), hyperlipidemia (HLD), prior heart attack (MI) and prior stroke (CVA), respectively. Among women without a comorbid condition, baseline annual mammography utilization was 47.3%. HTN and HLD were correlated with increased annual utilization [2.5 and 6.8 percentage points (pp)]. In comparison, prior MI and CVA were correlated with decreased annual utilization (-8.2 and -1.5 pp, not statistically significant in the latter). Results were similar for biennial utilization (3.0 and 7.6 pp increased utilization with HTN and HLD, respectively, and -6.5, and 0.1 pp decreased utilization for MI and CVA, respectively).

CONCLUSION

Screening utilization was increased in patients with HTN and HLD, and decreased in patients with prior MI and CVA. An understanding of how comorbid conditions influence screening may help better target specific populations and improve overall utilization of preventive care.

CLINICAL RELEVANCE/APPLICATION

HTN and HLD, comorbidities that require regular physician visits, are correlated with increased screening. However, prior MI or CVA, are correlated with decreased screening, possibly reflecting the effect of decreased life expectancy and increased morbidity. This is especially relevant as age-based guidelines fail to take into account individual comorbidities and life expectancy.

SSE02-06 Contrast-Enhanced Spectral Mammography (CESM) in the Screening Setting: Patient Preferences and Attitudes

Monday, Nov. 26 3:50PM - 4:00PM Room: E450B

matthew.miller@virginia.edu

PURPOSE

Contrast-enhanced spectral mammography (CESM) is an emerging imaging tool that has been shown to have greater sensitivity than conventional mammography and equal sensitivity with improved specificity relative to breast MRI in the diagnostic setting. Ongoing studies are evaluating CESM performance in the screening setting, but little is known regarding whether patients would agree to its use and the associated risks in screening. Our study aims to evaluate the attitudes and concerns of patients regarding

the use of CESM in a screening setting.

METHOD AND MATERIALS

In this IRB-approved HIPAA-compliant prospective study, patients with prior mammograms demonstrating heterogeneous or extremely dense breasts presenting for screening mammography were invited to complete a survey. Patients were asked to rate their perception of personal breast cancer risk compared to peers and their level of concern related to screening callbacks, radiation exposure, and contrast allergies, and then identify which factors might deter them from getting adjunct screening exams such as CESM.

RESULTS

512 patients with dense breasts undergoing screening mammography completed surveys. While 27% of surveyed patients reported previously having been called back from screening for a diagnostic workup, a majority (63%) expressed little or no concern for callbacks leading to additional imaging or biopsy. Most patients (63%) felt it was likely or very likely that cancer could be missed on their mammogram, but only 9% had undergone adjunct screening exams in the past 3 years. The most commonly cited deterrents to undergoing adjunct screening were cost (69%), pain (35%), and concern for an increased likelihood of having a biopsy or surgery recommended (32%). When asked to select from several hypothetical adjunct screening modality choices, patients reported a strong preference (63%) for a test that is most likely to detect their cancer, even if this would require IV-line placement. Only 5% preferred a common but less sensitive test that did not require IV-line placement.

CONCLUSION

Our study suggests that women with dense breasts may accept CESM as an adjunct screening exam and may actually prefer it over screening MRI or US given its relatively high sensitivity and low cost.

CLINICAL RELEVANCE/APPLICATION

Women with dense breasts may accept CESM as an adjunct screening exam given its sensitivity and low cost.

zhanglei4302@hotmail.com

PURPOSE

The aim of this study was to conduct a statistical analysis of low-radiation-dose coronary computed tomography screening for coronary artery calcium score (CACS) to determine the correlation of the CACS with age, sex, systolic blood pressure, diastolic blood pressure, low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), total cholesterol (TC), triglycerides (TG), uric acid (UA) and creatinine (Cr), as well as to investigate the predictive value of these traditional risk factors for coronary artery disease.

METHOD AND MATERIALS

There were 646 patients with chest pain or suspected coronary atherosclerosis, a clinical history, smoking habit, symptoms, high blood pressure, and high blood sugar. The following biochemical parameters were assessed: LDL-C, HDL-C, TC, TG, UA, and creatinine. All patients underwent a CT scan for coronary artery calcium score analysis. The scan was then analyzed in relationship to CACS levels and the above items for all patients.

RESULTS

In total, 326 patients were male (59.8%), and 219 patients were female (40.2%). The average age was 69.1 ± 10.2 years, and the mean CACS was 485 ± 814. Significant correlations of CACS with UA ($r = 0.1518$, $P < 0.05$) and creatinine ($r = 0.2752$, $P < 0.05$) were found. According to the multivariate Cox regression analysis, after adjusting for demographic characteristics and other serum parameters, serum UA levels (odds ratio [OR], 1.003, 95% confidence interval [CI], 1.001-1.005, $p = 0.003$) and creatinine levels (OR, 1.002, 95% CI, 0.999-1.005, $p = 0.002$) qualified as independent discriminators of the severity of coronary artery calcification.

CONCLUSION

We propose the need for identifying and managing UA and creatinine abnormalities to reduce excess coronary artery disease (CAD) risk. This proposal remains to be formally tested in a prospective study.

CLINICAL RELEVANCE/APPLICATION

The severity of coronary artery calcification score may indicated the UA and creatinine abnormalities in the blood.

SSE03-03 Feasibility Study of Coronary Computed Tomography Angiography in Patients with Free-Breathing Using 256-Detector CT

Monday, Nov. 26 3:20PM - 3:30PM Room: N229

Participants
Zhuo Liu, Beijing, China (*Presenter*) Nothing to Disclose
Nan Hong, MD, Beijing, China (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

liuzhuormyy@sina.cn

PURPOSE

To evaluate the feasibility of coronary computed tomography angiography (CCTA) in patients with free-breathing using 256-detector CT.

METHOD AND MATERIALS

616 patients underwent CCTA without heart rate control. 325 examinations were performed during free-breathing (group A), and the remaining 291 were performed during breath-holding(group B). The image quality scores were defined as 1 (excellent), 2 (good), 3 (adequate), and 4 (poor). 22 patients in group A and 24 in group B also underwent invasive coronary angiography (ICA) after CCTA within two weeks. The image quality score, diagnostic performance using ICA as reference, signal-to-noise ratio (SNR), and effective dose (ED) were compared between the two groups.

RESULTS

Mean heart rate during scanning was 70.8±13.8 bpm in group A and 70.7±13.2 bpm in group B (P=0.950). No significant differences were observed in the quality score between breath-holding and free-breathing groups (1.10±0.31 vs. 1.12±0.33; P=0.647). The SNR, effective dose were not significantly different between the two groups. In a segment-based analysis, the sensitivity and specificity in the detection of coronary stenosis of more than 50% were 82.1% and 96.8%, respectively in the breath-holding group and 82.2% and 96.6%, respectively in the free-breathing group with no significant differences for these parameters between the two groups.

CONCLUSION

CCTA for patients without heart rate control and with free-breathing using 256-detector CT showed no significant difference in image quality and diagnostic accuracy compared with patients with breath-holding.

CLINICAL RELEVANCE/APPLICATION

In patients without heart rate control, CCTA can be acquired during free breathing without substantial loss of image quality when using a 256-detector CT.

SSE03-04 Prognostic Value of Delayed Enhancement Imaging by Cardiac Computed Tomography in Predicting Major Adverse Cardiac Events in Patients with Suspected Coronary Artery Disease

PURPOSE

Myocardial CT delayed enhancement (CTDE) shares the same pathophysiological principle with late gadolinium enhancement MRI, and allows for infarct detection and viability assessment. However, the prognostic value of CTDE is unknown. The purpose of this study was to investigate whether the presence of delayed enhancement (DE) detected by CT is an independent predictor of major adverse cardiac events (MACEs) in patients with suspected coronary artery disease (CAD).

METHOD AND MATERIALS

We studied 429 consecutive patients with suspected CAD who underwent coronary CT angiography (CTA) and CTDE. Patients with known previous myocardial infarction (MI), percutaneous coronary intervention, coronary artery bypass surgery were excluded. MACEs were defined as severe cardiac events (cardiac death, nonfatal MI, unstable angina, heart failure necessitating hospitalization) and late revascularization (>180 days after CT examination). CTA results were divided into obstructive (>=50% luminal narrowing), mild (<50%), or no CAD groups. The Cox proportional hazards model was used to investigate the relationship between conventional clinical risk factors, coronary calcium sore and coronary CTA result and MACEs.

RESULTS

Follow-up information was obtained in 389 of the 429 patients (91%). DE was observed in 72 of the 389 patients (19%). During a median follow-up of 26 months, 24 cardiac events (2 cardiac death, 2 MI, 2 unstable angina, 6 heart failure and 12 late revascularization) were observed. When adjusted for obstructive CAD, the presence of DE maintained a significant association with risk of all cardiac events (adjusted hazard ratio, 5.9; $p< 0.0001$) and severe cardiac events (adjusted hazard ratio, 14.2; $p= 0.0002$). Kaplan-Meier curves demonstrated a significant difference in event-free survival between patients with DE and those without for severe cardiac events (log-rank test, $p< 0.0001$), as well as for all cardiac events (log-rank test, $p< 0.0001$).

CONCLUSION

The presence of CTDE was an independent predictor of MACEs and severe cardiac events in patients with suspected CAD among common clinical risk factors and coronary CTA findings.

CLINICAL RELEVANCE/APPLICATION

Acquisition of CTDE following coronary CTA seems to be useful since CTDE provides additional prognostic information in patients with suspected CAD.

PURPOSE

Reports exist of the acceptance rates of CCTA for FFRCT analysis from trials performed in academic centres, however real world data is lacking. The aim of the current study was to examine the acceptance rate, and the factors associated with rejection for FFRCT analysis.

METHOD AND MATERIALS

All clinical CCTAs referred between July 2016 and March 2018 for HeartFlow FFRCT analysis were included. Metadata from the submitted CCTAs was used to extract information on patient factors, scanner type, acquisition parameters and dose while HeartFlow FFRCT analysis data was used for quantification of aortic enhancement.

RESULTS

Of 10,621 CCTAs submitted, 9,524(89.7%) were accepted for FFRCT analysis. Of the 1,097 rejected: 205(18.7%) were for technical limitations of the submitted data (slice thickness/spacing >=1mm, pixel size >=0.5mm); 181(16.4%) due to the presence of stents, bypass grafts, other cardiac hardware; and 711(64.8%) for image quality. Patient factors associated with rejection were: higher heart rate (64.0(IQR 12.3) vs. 59.0(IQR 10.0) bpm, p<0.001) and heart rate variability (9.0(IQR 21.0) vs. 8.0(IQR 10.0) bpm, p<0.001). Technical factors associated with rejection were: retrospective acquisition (54% vs 31% retrospective, p<0.001), systolic phase acquisition (25% vs. 12% systolic, p<0.001), higher slice thickness (0.63(IQR 0.15) vs. 0.63(IQR 0.07) mm, p<0.001), higher pixel size (0.43(IQR 0.09) vs 0.40(IQR 0.06) mm, p<0.001), lower aortic attenuation (368(IQR 147) vs. 431(IQR 167), p<0.001) and higher kVp (120(IQR 0) vs. 120(IQR 20) kVp, p<0.001). BMI (p=0.9), and image noise (p=0.07) were no different in those with accepted or rejected CCTAs. On logistic regression, heart rate, systolic image acquisition, aorta contrast, pixel spacing, and slice thickness all remained significant predictors of rejection for image analysis (p<0.001 for all).

CONCLUSION

Almost 20% of FFRCT rejection could be avoided by stringent post processing protocols, and a further 20% by appropriate case selection. For the remainder, utilization of CTFFR requires similar strict heart rate and contrast timing image optimization strategies required of CCTA.

CLINICAL RELEVANCE/APPLICATION

Stringent patient preparation, case selection and post processing strategies hold potential to improve the opportunity for successful utilization of FFRCT analysis.

PURPOSE

to investigate coronary atherosclerosis and flow physiology by coronary computed tomography angiography (CTA) including 3D computational fluid dynamics (CFD) (noninvasive CT-FFR) in endurance athletes compared to inactive controls (CR)

METHOD AND MATERIALS

90 subjects (age 56.2y, 26 females) were examined with 128-dual source coronary CTA. Coronary arteries were evaluated per

90 subjects (age 58.2), 20 females) were examined with 128 dual source coronary CTA. Coronary arteries were evaluated per segment (AHA-16-s-classification) for CAD:1) Stenosis severity (CADRADS 0-5) 2) Total plaque burden (segment involvement score, SIS) and G-score: a new indicator for non-calcified plaque burden3) High risk plaque features (LAP-HU, spotty calcification, NRS, RI) were quantified4) Coronary Fractional Flow reserve (FFR) was remodelled by CFD Study design was retrospective (matched case controlled, 45 endurance-athletes vs 45 CR)The endurance group was defined as "regular" training (cycling, running or others) for least 1h per unit and >=3 times per week. Years of training were recorded.

RESULTS

Coronary stenosis severity (CAD RADS) score was lower in the endurance group vs CR (1.44 vs 2.1, p=0.007). Total and non-calcified plaque burden (SIS and G-score) were also sign. lower (1.8 vs 3.3 ; p=0.003 and 3.5 vs 6.6, p=0.002) while calcium score was trended lower only (38.9 AU vs 137.2 AU, p=0.06)HRP prev. was eminenty lower in athletes (5 vs 14 (2.2% vs 31.1%) p=0.02), and NRS (4 vs 7), resp.Non-calcified and total plaque burden (G-score and SIS) were strongest and significantly correlated with declining distal FFR (RCA S4:r=-0.32 and r=-0.3; p=0.03 and p=0.02, LAD S8 r=-0.2,p=0.09 for G-score), while calcium score was not (S4:p=0.07 and S8:p=0.861, Spearman), in the entire cohort. There was no difference in distal FFR between athletes vs CR (p= 0.532, 0.203, 0.358, 0.343 ANOVA)

CONCLUSION

Regular endurance training (min. 1 h and >=3x/week) reduces CAD burden (coronary stenosis severity, total and non-calcified plaque burden and most eminenty, high-risk plaques). Total and non-calcified plaque burden (G-score) rather than coronary calcium predicts distal coronary flow limitations in both athletes and inactives

CLINICAL RELEVANCE/APPLICATION

Regular endurance training reduces CAD burden and risk, with a dominant effect on high-risk plaque. We describe a novel non-calcifying plaque burden score (G-score),which is easy- to-implement into clinical structural reporting and potentially predicts myocardial ischemia

PURPOSE

Cardiac MRI (cMRI) is the gold standard for quantitative cardiac evaluation. However, it requires specialized training and expertise to perform. To advance the accessibility and quality of cMRI, we developed a convolutional neural network (CNN) to localize key cardiac landmarks to guide plane prescription. We hypothesize that CNN-based landmark localization may generate similar imaging planes to those acquired by a dedicated cardiac technologist.

METHOD AND MATERIALS

With HIPAA-compliance and IRB waiver of informed consent, we retrospectively collected clinical cMRIs performed at our institution from February 2012 to June 2017, including 472 short axis (SAX) and 892 long axis (LAX) cine series. Anatomic landmarks were annotated by expert radiologists. U-Net CNNs were implemented to predict the location of these structures using heatmap localization. Data was split into 80% of cases for training and 20% for testing. SAX, 4, 3, and 2 chamber planes were computed from predicted anatomic localizations. We analyzed performance of localization by calculating distances between predictions and ground truth annotation, and report mean error and standard deviations. We assessed plane prescription by calculating the angle difference between CNN-predicted planes and those acquired by the technologist. Angle bias, mean error, and standard deviations are reported for each plane orientation.

RESULTS

From LAX images, the mean distance between annotation and predicted location was 7.70±5.90 mm for apex and 5.70±4.02 mm for the mitral valve. For SAX images, the mean distance was 11.99±7.80 mm for aortic valve, 10.20±5.65 mm for mitral valve, 12.56±5.10 mm for pulmonic valve, and 11.99±6.43 mm for tricuspid valve. For SAX stack prescription, average angle bias, mean error, and standard deviations were -7.80°, 7.80°±5.44°. For LAX prescriptions, average angle bias, mean error, and standard deviations were 5.64°, 6.65°±5.22° for 4-chamber, 10.86°, 11.95°±8.02° for 3-chamber, and 4.21°, 7.46°±7.36° for 2-chamber.

CONCLUSION

CNN-based anatomic localization is a feasible strategy for planning cMRI imaging planes. In this study, we show that this approach can produce imaging planes similar to those chosen by dedicated cardiac technologists.

CLINICAL RELEVANCE/APPLICATION

CNNs have the potential to improve the quality and accessibility of MRI, and may even benefit complex examinations like cardiac MRI, which require multiple double oblique image planes.

SSE04-02 Deep Learning for Accelerated CMR Image Reconstruction

PURPOSE

CMR acquisition is inherently time consuming and requires multiple breath-holds, which is not only challenging for many patients, but it also makes the modality susceptible to motion artefacts. The aim of this study is to accelerate the CMR data acquisition by reducing the amount of k-space data needed for reconstructing images from undersampled data.

METHOD AND MATERIALS

Fully sampled, short-axis cardiac cine MR scans from 10 volunteers were acquired. Each scan contains a single slice SSFP acquisition with 30 temporal frames, resolution of 256x256 pixels, FOV of 320x320 mm with slice thickness 10mm. The recombined single-coil images were retrospectively undersampled respecting a linear frequency/phase encode structure, while the central 8 lines in k-space were always included. Deep learning-based iterative denoising algorithms are proposed: 3D-convolutional neural network (CNN) and 2D-convolutional recurrent neural network (CRNN). The networks were trained to directly output clean image from the aliased image. The proposed methods were compared to state-of-the-art compressed sensing approaches: kt-FOCUSS and kt-SLR. The methods were evaluated using peak signal-to-noise ratio (PSNR) and reconstruction speed. We considered acceleration factors 6 and 9 and performed 3-fold cross validation.

RESULTS

The networks were trained within three days on GPU GeForce GTX 1080. Even from small number of training subjects one could train a network that works well on test data. For acceleration factor 6, PSNR was 32.5, 34.6, 37.2 and 37.37 dB for kt-FOCUSS, kt-SLR, CRNN and CNN respectively. For acceleration factor 9, the numbers were 29.7, 31.4, 33.3 and 34.95 dB respectively. The reconstruction speeds were 15, 450, 6 and 10 seconds respectively.

CONCLUSION

We have proposed deep learning-based approaches for CMR image reconstruction, which both outperform current state-of-the-art both in terms of speed and reconstruction quality for single-coil, retrospective undersampling study.

CLINICAL RELEVANCE/APPLICATION

The method will be able to accelerate the CMR acquisition, which reduces burden on patients and improves image quality. In future, parallel imaging extension and implementation on scanner is expected.

SSE04-03 Multiparametric Cardiovascular Magnetic Resonance Imaging Assessment in End Stage Renal Disease Patients with Preserved Left Ventricular Ejection Fraction

Monday, Nov. 26 3:20PM - 3:30PM Room: N226

PURPOSE

Early detection of cardiac dysfunction in end stage renal disease (ESRD) patients is beneficial but challenging. Our study aimed to evaluate myocardial strain and tissue characteristic changes by cardiovascular magnetic resonance (CMR) imaging in ESRD patients with preserved left ventricular ejection fraction (LVEF), especially focused on those with no echocardiographic evidence of diastolic dysfunction.

METHOD AND MATERIALS

29 ESRD patients (17 males; mean age 44±11 years) with LVEF >50% in ultrasonagraphy and 43 healthy volunteers (24 males; mean age 43±10 years) underwent CMR imaging including cine, native T1 and T2 mapping. LV function, global LV strains as well as LV myocardial native T1 and T2 of the mid-cavity slice were measured and compared between the two groups. Correlations between LVMASS and CMR parameters were analyzed. According to ASE/EACVI recommendations for the evaluation of LV diastolic function by echocardiography, ESRD group were divided into normal diastolic function subgroup (n=11) and diastolic dysfunction subgroup (n=18). CMR parameters were compared among the two subgroups and the healthy group.

RESULTS

Native T1 and T2 were statistically higher in ESRD group (1296.2±38.4ms, 44.0±2.8ms) than healthy group (1260.1±51.9ms, 41.0±1.7ms; p=0.002, p<0.001). LV Global longitudinal strain (GLS) and global circumferential strain (GCS) were statistically

impaired in ESRD group (-14.5±2.9%, -16.4±3.0%) compared with the healthy group (-16.5±2.2%, -18.2±2.5%; p=0.002, 0.008). Increased LVMASS was strongly associated with impaired LV GLS and GCS (r= 0.72, 0.73; p<0.001) in ESRD group. In subgroup with normal diastolic function, T2 (43.2±1.5ms) and LV GLS (-14.3±3.0%) were statistically different from those in the healthy group (p=0.002, 0.008), while native T1 and LV GCS were similar with those in the healthy group.

CONCLUSION

ESRD patients with preserved LVEF demonstrated higher myocardial native T1, T2, and impaired LV GLS and GCS compared with healthy people. Myocardial edema and decreased myocardial compliance might exist in ESRD patients with preserved LVEF and normal diastolic function, as indicated by higher T2 and impaired LV GLS.

CLINICAL RELEVANCE/APPLICATION

Early stage of myocardial fibrosis, edema and decreased myocardial compliance might exist in ESRD patients with preserved LVEF, even when their diastolic function is normal on echocardiography.

SSE04-04 Subharmonic Aided Pressure Estimation (SHAPE) for Obtaining Intra-Cardiac Pressures Noninvasively in Real-Time: Preliminary Results

PURPOSE

Subharmonic aided pressure estimation (SHAPE) utilizes subharmonic signals from ultrasound contrast agents for pressure estimation. The purpose of this work was to evaluate the efficacy of intra-cardiac SHAPE using Definity (Lantheus Medical Imaging) and Sonazoid (GE Healthcare) microbubbles in patients scheduled for cardiac catheterization procedures.

METHOD AND MATERIALS

Patients scheduled for left and/or right heart catheterization procedures were recruited into this IRB-approved study. During the catheterization procedure, 15 patients received an infusion of Definity (2 activated vials mixed in 50 mL saline; 4-10 mL per minute) and 3 patients received a co-infusion of Sonazoid (infusion rate (mL/hour) = 0.18 x body weight in kg) and saline (120 mL/hour). During contrast infusion, the patients were scanned using a customized interface developed on a SonixTablet scanner (BK Ultrasound; interface developed using C/C++ and cross-platform Qt libraries (The Qt Company)) to determine optimum incident acoustic output (IAO; from a set of 16 pre-configured acoustic outputs coded from 0 or minimum to 15 or maximum) eliciting ambient pressure sensitive growth phase subharmonics for SHAPE, on a per-patient basis. Previously determined optimal parameters for Definity (ftransmit: 3.0 MHz; a chirp down pulse) and Sonazoid (ftransmit: 2.5 MHz; square wave pulse) were used for data acquisition. Correlation coefficient between the SHAPE and pressure catheter data was computed using MATLAB (2016A, The MathWorks, Inc.).

RESULTS

The IAO's at which the best correlation coefficient obtained between the SHAPE and pressure catheter data varied on a per-patient basis from coded values of 3 to 15 (patient BMI range: 22.7-64.6). Data with Definity infusion showed that the correlation coefficient between SHAPE and pressure catheter for the left ventricle (LV) was -0.8 ± 0.03 (mean ± standard deviation; n = 10) and for the right ventricle (RV) was -0.8 ± 0.08 (n = 12). Data with Sonazoid infusion showed the correlation coefficient between SHAPE and pressure catheter for the LV was -0.8 ± 0.04 (n = 2) and the RV was -0.8 (n = 1).

CONCLUSION

Preliminary results indicate a good correlation (correlation coefficient range: -0.7 to -0.9) between SHAPE and pressure-catheter based intra-cardiac pressures.

CLINICAL RELEVANCE/APPLICATION

Intra-cardiac SHAPE may become an effective noninvasive alternative to cardiac catheterization procedures.

SSE04-05 Transient Ischemic Dilation and Coronary Artery Disease Burden in Cardiac MRI

Monday, Nov. 26 3:40PM - 3:50PM Room: N226

Participants
Jerry Yan, MD, Milwaukee, WI (*Presenter*) Nothing to Disclose

Jason Rubenstein, MD, Milwaukee, WI (*Abstract Co-Author*) Nothing to Disclose
Andrew E. Kott, MD, Nashville, TN (*Abstract Co-Author*) Nothing to Disclose

jmyan@mcw.edu

PURPOSE

Transient Ischemic Dilation (TID) is a well-established finding in nuclear myocardial perfusion imaging (MPI) and is a marker for coronary artery disease (CAD) severity. Stress perfusion cardiac MRI (CMR) offers significantly improved spatial and temporal resolution relative to MPI and allow for direct measurement of the LV wall cavity dimensions. Despite these advantages, CMR-derived TID ratios are not well established and thus not utilized in the clinical setting for CAD severity. The aim of this study was to confirm whether TID occurs during stress perfusion CMR and define a TID ratio that predict the presence and severity of CAD.

METHOD AND MATERIALS

Patients who underwent a complete stress CMR from 2012-2016 were included in the study. Imaging studies were analyzed and stress and rest left ventricular (LV) area at three myocardial cross-sections, basal, mid, and apex, was recorded. Coronary angiographic data for all patients with this information available was reviewed. TID ratio was calculated as the LV cavity area minus papillary muscles at stress versus rest. Global TID ratio was calculated by taking the mean of the segments (basal, mid, and apex) for each patient. Patients were classified into High Risk group if angiography results show >= 70% stenosis in the proximal LAD, >= 70% stenosis in the Left Main, >=90% lesion in more than 2 major vessels, or prior CABG with >=70% graft lesion. Unpaired t-test was used to compare mean values of High Risk and Low Risk groups and a ROC analysis was performed to determine the global TID ratio that differentiated patients with High Risk CAD versus Low Risk CAD.

RESULTS

One hundred forty three patients underwent stress CMR. Fourteen patients met criteria for High Risk CAD on coronary angiography, while the remainder had either negative stress or positive stress with low risk CAD. Mean Global TID ratio for high risk group was 1.18 vs 0.98 in the low risk group (p = 0.004). AUC in the ROC analysis was 0.734 (p=0.004). Associated criterion maximizing specificity revealed global TID ratio > 1.16 with a sensitivity of 57% and specificity of 85%.

CONCLUSION

Significant dilation in the LV area at stress occurs when severe CAD is present compared to rest.

CLINICAL RELEVANCE/APPLICATION

A global stress to rest ratio of 1.16 in cardiac stress MRI may provide an additional marker for identifying high-risk multi-vessel CAD.

SSE04-06 Is Cardiac MR Indispensable for Assessing the Cardiac Mass?: Based on the Review of 10-Years of Hospital Records

Monday, Nov. 26 3:50PM - 4:00PM Room: N226

Participants
Ji Eun Park, Seongnam, Korea, Republic Of (*Presenter*) Nothing to Disclose
Eun Ju Chun, MD, PhD, Seongnam-Si, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Jeong A Kim, MD, Goyangsi, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Jin Young Yoo, MD, Cheongju, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Yeonyee E Yoon, Sengnam, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Although cardiac magnetic resonance (MR) is useful for assessing cardiac mass, it has limited to use as the first modality because of high cost and long scan times. Therefore, we aimed to evaluate how MR is effective in assessing the cardiac mass based on the review of 10-years of hospital records.

METHOD AND MATERIALS

We hypothesized that cardiac mass is firstly detected with echocardiography, and further evaluated with CT and MR. On the basis of echocardiography from 2008 to 2017 in single tertiary hospital, we searched patients with cardiac mass using ICD code and keywords. Cardiac mass was classified by the location (intracardiac, valve and extracardiac) and evaluated the transferred ratio to next modality (CT or MR) from echocardiography according to mass location. Finally, we evaluated why the clinician performed MR and how successful that goal was achieved.

RESULTS

In a total of 718 adults (390 males, 62.6±18.7 years) with cardiac mass (282 intracardiac mass, 262 valve mass, 174 extracardiac mass) which detected on echocardiography, 406 patients (56.5%) were performed CT. Among them, CT performed ratio is highest for extracardiac mass (92.0%) followed by intracardiac mass (66.0%) and valve mass (22.9%), sequentially. MR was performed in 64 patients (8.9%); 16 patients with directly performed MR, 48 patients were performed MR after CT. Role of MR in assessing the cardiac mass was as follows; tissue characterization (n=36), differentiation of thrombus from tumor (n=15) and detection of invasiveness (n=25). After MR, the successful rate which met the goals of MR was highest for detection of invasiveness (92.0%), followed by differentiation of thrombus (80.0%) and tissue characterization (61.1%).

CONCLUSION

Valve mass may be sufficient with echocardiography, and extracardiac mass requires CT to assess the extent. CMR is useful for determine invasiveness and differentiate thrombus from tumor than tissue characteristics

CLINICAL RELEVANCE/APPLICATION

From this review of our data, the efficacy of CMR for assessing cardiac mass might be higher to determine the invasiveness and differentiate the thrombus from tumor than to detect tissue characteristics.

para2727@gmail.com

PURPOSE

As the quantitative airway analysis has been evolved, the effect of smoking has been established. However, the generation-based smoking effect where inter-subject variabilities are normalized is rarely known. The purpose of this study is to evaluate a prediction model of airway parameters, and further to investigate generation-based structural and functional airway alterations in smokers with the derived normalization scheme.

METHOD AND MATERIALS

68 smokers and 174 nonsmokers with inspiratory/expiratory CT findings, and normal pulmonary function tests were included in the study. VIDA Apollo software (Coralville, IA) was used for the airway size analysis. To control inter-subject variability, multiple linear regressions of tracheal wall thickness (WT), diameter (D), and luminal area (LA) were used for the normalization of airway parameters considering the effects of age, sex and height. Using this scheme, each airway parameter was normalized by individual predicted values, and normalized WT (WT*), D (D*), LA (LA*) from the 1st to 8th generation of each lobe were compared between smokers and non-smokers.

RESULTS

LA* and D* decreased and WT* increased in the smokers after normalization ($p<0.05$), which was not observed before normalization. The wall thickness of the segmental airways in smokers was not changed between inspiration and expiration (WT*ins-WT*exp= 0.01±0.01), whereas that in non-smokers was thicker at expiration than inspiration (-0.02±0.01). Besides, airways at the 3rd generation showed significant wall thickening in smokers than nonsmokers ($p=0.003$).

CONCLUSION

Quantitative CT assessment using a normalization scheme suggest that smoking may induce airway wall thickening and reduce changes of wall thickening during respiration, which means a decrease in airway wall compliance. Generation-based analysis showed that the 3rd generation is most affected by smoking.

CLINICAL RELEVANCE/APPLICATION

When it comes to the effect of smoking, it is important to perform normalization and focus on wall thickening of segmental airways.

SSE05-02 Enhanced Evaluation of Tracheomalacia with Use of Cyclic Ultra-low Dose Dynamic Expiratory CT

PURPOSE

The percent tracheal area narrowing (%TN) between paired inspiration CT and dynamic expiratory CT (DECT) is used to diagnose and grade tracheomalacia (TM). At our institution this is done clinically with the maximum %TN on either of two consecutive ultra low dose DECTs (mDECT). This study aims to evaluate the implications of mDECT vs. single DECT in TM diagnosis and grading.

METHOD AND MATERIALS

CT studies for evaluation of TM from 2017 performed at a single imaging site were retrospectively evaluated. CT protocol of one routine inspiratory chest CT and two consecutive ULD (100 kVp, fixed mA 10) DECT. The %TN for each DECT was obtained by comparing the greatest percent tracheal narrowing on anatomically matched expiration and inspiration CT, measured independently for DECT 1 and 2. Tracheal area was measured manually delineating the luminal contour of the trachea with the free-hand PACS ROI tool on 2.5 mm axial slices by a thoracic fellowship trained radiologist. The presence of TM (>70 %TN) and its severity (negative <70%, mild 70-80%, moderate 80-90%, severe >90%) were assessed. The mean %TN, percent of patients with TM diagnosis, and distribution of TM severity between DECT1, DECT2 and mDECT were analyzed using paired 2-tailed t-test, 2-tailed binomial proportions test, and chi-squared test, respectively.

RESULTS

184 patients (41% male) with mean age of 64 were analyzed. Mean radiation dose for each DECT phase was 0.07 mSv with all studies deemed diagnostic. mDECT demonstrated 57 mean %TN, 10% greater than DECT1 and 6% greater than DECT2 (each $p<0.001$), with DECT2 9% greater mean %TN than DECT1 ($p<0.05$). 40% Percentage of patients with TM diagnosis with mDECT (40%) was 10% greater than DECT1 or 2 (each 30%, $p<0.05$). mDECT (109 negative, 31 mild, 24 moderate, and 20 severe) had significantly greater number of patients diagnosed with TM with a significantly more severe distribution of disease than DECT1 (128, 27, 21, 12) or DECT2 (127, 21, 21, 15), (each $p<0.05$) without significant differences between DECT1 and 2.

CONCLUSION

For CT evaluation of TM, mDECT demonstrated low patient radiation dose with an increase in mean %TN, a higher rate of TM diagnosis and a more severe distribution of disease than a single DECT phase alone.

CLINICAL RELEVANCE/APPLICATION

CT evaluation of TM with two ultra low dose DECTs should be considered to diagnose and grade TM.

SSE05-04 Correlation of CT Small Airway Measurement with Clinical and Inflammation Factors in Asthma Patients

Monday, Nov. 26 3:30PM - 3:40PM Room: N230B

Participants
Meijiao Li, MD, Beijing, China (*Presenter*) Nothing to Disclose
Wei Guo, Beijing, China (*Abstract Co-Author*) Nothing to Disclose
Huishu Yuan, Beijing, China (*Abstract Co-Author*) Nothing to Disclose

newgljyk@163.com

PURPOSE

To evaluate the correlation of CT small airway measurement with clinical and inflammatory indicators in Asthma Patients.

METHOD AND MATERIALS

20 patients with asthma were enrolled, all received spiral CT, pulmonary function test, serum leptin, IgE and TGF-ß1, induced sputum cytology and MMP-9. Asthma Control Test (ACT) and smoking condition were recorded. At the end of 6th generation airway, adjusted by body surface area, Luminal diameter(LD), luminal area(Ai), wall thickness(WT) and wall area%(WA%)were measured. Inter-observer repeatability was estimated by intra-class correlation coefficients(ICC). Comparison of the CT airway indexes between groups of onset age<=12yrs and>12yrs, ACT well/partly controlled and poorly controlled, with and without smoking history, induced sputum Eos%<3% and >=3% were made. Correlations between CT airway measurements with clinical and inflammatory indicators were determined.

RESULTS

The ICC of LD, Ai , WT and WA% was 0.813, 0.923, 0.850, 0.958. In asthma patients, both LD and Ai were significantly lower in groups of onset age <=12yrs, patients with smoking history and induced sputum Eos%>=3% than corresponding groups(LD, t=-2.760, -2.459, -3.935, Ai, t=-2.851, -2.267, -4.492, all $P<0.05$). WA% was significantly higher in groups of induced sputum Eos%>=3% than the corresponding group($t=2.448$, $P<0.05$). LD and Ai had negative correlation with course of disease and induced sputum Eos%(LD, r=-0.512, -0.841, Ai, r=-0.489,-0.841, all $P<0.05$), and positive correlation with FEV1/FVC and serum leptin(LD, r=0.669, 0.533, Ai, r=0.681,0.552, all $P<0.05$). Ai also showed positive correlation with FEV1%($r=0.452$, $P<0.05$). WT and WA% were significantly negative correlated with FEV1/FVC and FEV1%(WT, r=-0.621, -0.483, WA% , r=-0.729, -0.548, all $P<0.05$). WA% also showed positive correlation with serum IgE and induced sputum MMP-9($r=0.509$, 0.636, all $P<0.05$).

CONCLUSION

CT airway indexes were found partially associated with asthma onset age, course of disease, smoking condition, serum leptin and IgE, induced sputum Eos% and MMP-9,. CT airway indexes showed correlation with FEV1/FVC and FEV1%.

CLINICAL RELEVANCE/APPLICATION

CT indexes of small airway were found associated with asthma onset age, course of disease, smoking condition, serum leptin and IgE, induced sputum Eos% and MMP-9, as well as FEV1/FVC and FEV1%.

SSE05-05 A Comparative Study of Performance Between Radiographers and Machine Learning Model (MLM) for Airway Measurement

PURPOSE

The purpose of this study is to compare the performance between radiographers and machine learning model of analyzing airway.

METHOD AND MATERIALS

Total 182 patients' thin slice CT data of KOLD cohort was used and their all airway branches were semi-automatically segmented by AView software (Coreline Soft, Co., Ltd, South Korea). 46,436 airway axial images were used to train MLM using DenseNet 201 that we changed the last DenseLayer to binary classification. All airway axial images were colored using integral-based half-band method and they were labeled as accept or reject to clarify and precise airway results. In randomly selected 50 axial images, accuracy was compared among two radiographers with 4-year experience on airway measurement and MLM. Cohen's Kappa was used to assess the inter-observers agreement and elapsed time was measured. T-test, in addition, was performed to compare airway results on 182 patients of KOLD cohort between one blinded radiographer and MLM.

RESULTS

The ROC analysis of the test data sets showed 0.92 of area under curve. In the 50 randomly selected airway axial images, Sensitivity, specificity of MLM were 0.96, 0.88 and its accuracy was 0.92. In radiographers, respectively, 0.86, 0.7 and 0.78 were shown (Cohen's kappa = 0.62). Elapsed time between two control groups, two radiographers and MLM, showed statistically significant difference (190.3 and 1.8 seconds, $p < 0.05$). The mean airway pi-10 and wall area percent showed no statistically significant difference (radiographer, 4.12 ± 0.89 mm, 66.43 ± 7.56 %; MLM, 4.15 ± 0.88 mm, 66.66 ± 7.35 %, $p > 0.05$, respectively).

CONCLUSION

Trained MLM showed no differences comparing with skilled radiographers in the results of airway measurement with short elapsed time. Consequentially, MLM measures all airway branches fully automatically without expert interactions, if airway segmentation well performed.

CLINICAL RELEVANCE/APPLICATION

The airway is considered as an imperative index of lung. Fully automatic airway measurement of whole branch would be more efficient for imaging biomarker in COPD patients.

SSE05-06 Catheter-Based Endobronchial Navigation with a Novel Cone Beam CT Airway Segmentation Platform to Reach Peripheral Lung in a Swine Model Without Bronchoscopy

Corporation

PURPOSE

To investigate the feasibility of catheter-based endobronchial navigation to peripheral lung without a bronchoscope using a novel Cone Beam CT (CBCT) image-guidance prototype in a swine model.

METHOD AND MATERIALS

All animal procedures were approved by the Animal Care and Use Committee. Swine (n=3) were placed under general anesthesia. Thoracic CBCT (FD20, Philips Healthcare) was imported into a workstation with prototype software (Philips) that provides for 3D airway segmentation, manual identification of targets and 3D navigation guidance superimposed on fluoroscopic imaging. Peripheral targets (bronchial subsegments) were identified. Catheter-based endobronchial navigation to targets was performed with 4 and 5 Fr catheters (Cook Medical) with varying shapes (e.g., C2, multipurpose, DAV) over 0.035' hydrophilic vascular guidewires of various curves and stiffness (Terumo). The primary endpoint was successful navigation of a catheter into a bronchial target. Success was assessed by catheter position on multiple X-ray images at preplanned C-arm angles and CBCT.

RESULTS

Catheter-based navigation to primarily 3rd and 4th order airway segments was successful in 11/13 tasks in the first two swine. Failure to navigate guidewires to distal targets occurred when the guide wire or catheter tip was too stiff with poor maneuverability or had a sub-optimal shape for the airway geometry. With optimization of device selection and imaging settings, catheter-based navigation to even more complex 4th and 5th order segments targets was successful in 8/11 tasks; navigation failures occurred due to suboptimal catheter or wire shape or stiffness for the target (n = 2) or suboptimal imaging settings (n=1). In these cases, operator adherence to predefined fluoroscopic imaging protocols also restricted identification of malposition and adjustments that might otherwise occur.

CONCLUSION

Catheter-based endobronchial navigation without a bronchoscope is feasible with CBCT 3D segmentation and image-guidance combined with fluoroscopy. Catheter and wire design, including size, shape and physical properties, are important predictors of navigation success, especially for more peripheral airway tasks.

CLINICAL RELEVANCE/APPLICATION

CBCT airway segmentation and guidance software may advance endobronchial catheter-based approaches for lung diagnostics and treatments beyond the reach of a bronchoscope. Catheter and wire selection impacts procedural success.

PURPOSE

We evaluated the correlation between organic parenchymal density in Hounsfield Units (HU) with the radiological alteration index (RAI) level as surrogate for postmortal alteration in postmortem computed tomography (PMCT).

METHOD AND MATERIALS

We retrospectively included 14 human cadavers (6 females, 8 males) undergoing whole body PMCT. RAI was assessed in 7 localizations reflecting the presence of gas. Based on the total RAI-score cadavers were divided into three groups. [Group 1: low RAI (total score: 0-30); Group 2: medium RAI (total score: 30-60) and Group 3: high RAI (total score: 60-100)]. Density values (HU) were measured in 8 different localizations (1. frontal lobe, 2. basal-ganglia, 3. myocardium, 4. pectoral muscle, 5. liver, 6. left kidney, 7. m. iliopsoas, 8. first lumbar vertebral body[L1]). Correlation between density values and RAI was tested.

RESULTS

7 cadavers were included in group 1 with a mean RAI-score of 8.9±9.8,4 cadavers in group 2 with a mean RAI-score of 36.5±6.7 and 3 cadavers in group 3 with a mean RAI-score of 83.7±14.8. Density measurements showed no significant difference between the three groups for all anatomic landmarks (frontal lobe: group 1: 43.4±6.5 HU vs. group 2: 46.1±5.8 HU vs. group 3: 46.4±6.4 HU; basal-ganglia: 43.7±5.3 vs. 41.8±4.8 vs. 44.7±6.8 HU; myocardium: 49.4±9.7 vs. 44.7±8.3 vs. 45.9±8.6 HU; pectoral muscle: 52.9±7.2 vs. 47,0±8.1 vs. 50.8±14.3; liver: 61.5±10.4 vs. 76.1±12.0 vs. 64.1±9.6; left kidney: 49.1±9.5 vs. 43.9±10.7 vs. 35.6±9.8; m. iliopsoas: 48.7±9.2 vs. 51.4±10.3 vs. 55.1±9.8; L1: 169.8±40.5 vs.165.8±46.8 vs. 141.9±30.0; $p > 0.05$ for all). There was no significant correlation between density measurements and RAI.

CONCLUSION

There was no correlation between RAI and density measurements in 8 evaluated organs irrespective of the patients' RAI index.

CLINICAL RELEVANCE/APPLICATION

CT organ density measurements cannot be reliably used to assess decay in postmortem CT.

SSE06-04 Diagnostic Value and Forensic Relevance of a Novel 3D-Reconstructions Method (Cinematic Rendering) in Postmortem Computed Tomography (PMCT)

PURPOSE

To evaluate the radiologic performance and forensic relevance of novel photorealistic 3D reconstructions (Cinematic Rendering) of traumatic injuries in comparison to conventional postmortem computed tomography (PMCT).

METHOD AND MATERIALS

22 human cadavers undergoing whole body PMCT on 3 different CT-scanners (Definition Flash, Edge and AS+, Siemens, Germany) after traumatic death were retrospectively analyzed. A total of 38 pathologies were reconstructed with 3D Cinematic Rendering mode and conventional multiplanar CT in all 3 dimensions (bone and soft tissue window). 3D reconstructions of pathologies were performed with the preset gallery settings 'Patient Marking CT VRT' and 'Myocardium dark'.Two forensic pathologists evaluated the images according to their expressiveness and judicial relevance on a five-level scale (1: high expressiveness; 5: low expressiveness) and decided whether Cinematic Rendering reconstructions are suitable for judicial reviews or not. Two radiologists analyzed all images due to the detection rate of pathologies in both, Cinematic Rendering reconstructions and PMCT.

RESULTS

Forensic estimation: Mean value expressiveness of Cinematic rendering reconstructions: forensic Reader 1: 2.4±1.1 (range:1-5); forensic Reader 2: 1.9±1.2 (range: 1-5); total: 2.1±1.2 (range:1-5). Mean value expressiveness of conventional PMCT: forensic Reader 1: 4.1±1.1 (range: 2-5); forensic Reader 2: 3.7±1.1 (range: 1-5); total: 3.9±1.1 (range: 1-5). Concerning forensic interpretation and demonstration aspects results showed that Cinematic Rendering reconstructions were significantly more expressive than conventional PMCT images ($p<0.05$). Regarding the radiologic detection rate of all pathologies the evaluation of both radiologists lead to no significant difference between 3D reconstructions and original CT slices for all pathologies.

CONCLUSION

Cinematic Rendering reconstructions are more helpful for forensic pathologists than standard PMCT images. Concerning the detection of pathologies by radiologists, there is no significant difference between PMCT and Cinematic Rendering reconstructions. Essentially, Cinematic Rendering is suitable for demonstration and detection of relevant findings.

CLINICAL RELEVANCE/APPLICATION

Cinematic Rendering is a good method for visualizing pathologies,e.g. fractures or soft tissue injuries in judicial reviews and helps forensic pathologists correlate the findings with autopsy results.

SSE06-05 Utilizing the Broken Circle Sign: A New Method for Detecting a Hill-Sachs Lesion on an Internal Rotation Shoulder Radiograph

PURPOSE

A Hill-Sachs (HS) lesion is a potential indicator of shoulder joint instability. Diagnosis is based on a flat or concave defect in the superior aspect of the humeral head on an internal rotation (IR) radiograph but the finding is often subtle. The purpose of this study was to describe a new method designed to increase the sensitivity for HS lesions.

METHOD AND MATERIALS

A retrospective search for patients who sustained a prior dislocation, were evaluated with x-rays, and had a HS lesion on MRI was performed for a 10-yr period. In Part 1, only the AP IR x-ray was utilized and these were randomized with controls. Three readers were asked to independently score all x-rays with 'yes' if they detected a HS lesion or 'no' if they did not or were unsure. One month later, the readers were taught the Broken Circle Sign, and re-scored the x-rays using the new technique. In Part 2, 15 MRI-confirmed cases of HS lesions that were missed on initial review were mixed with normal x-rays and shown to 17 residents individually before and after teaching the new method. A paired t-test was used to evaluate the differences in sensitivity, specificity, accuracy, positive predictive value (PPV) and negative predictive value (NPV).

RESULTS

A total of 256 patients met the selection criteria (199 men, 57 women; age range: 15-82 yrs, mean: 31.2 yrs). There were 127 right and 129 left shoulders. In Part 1, sensitivity for all 3 readers increased by an average of 20.6% (54.1% to 74.7%; p<0.02), accuracy increased by an average of 7.4% (69.1% to 76.5%; p<0.05), and NPV increased by an average of 10.8% (62.4% to 73.3%; p<0.005). In Part 2, sensitivity for the residents increased by an average of 20.4% (54.1% to 74.5%; p<0.0001), accuracy increased by an average of 14.6% (65.1% to 79.7%; p<0.0001), and NPV increased by an average of 15.3% (41.6% to 56.9%;p<0.001) independent of their level of training. Only 2 residents did not improve due to high initial scores in sensitivity and accuracy.

CONCLUSION

The Broken Circle Sign is a simple tool that helps to increase the conspicuity of a Hill-Sachs lesion on internal rotation shoulder radiographs. It appears to increase the sensitivity, accuracy, and NPV at all levels of training.

CLINICAL RELEVANCE/APPLICATION

The Hill-Sachs lesion occasionally is a difficult diagnosis to make on radiographs. The Broken Circle Sign is a simple method that can aid in increasing the diagnostic acumen for this abnormality.

SSE06-06 Radiology "Forensics": Determination of Age and Gender from Chest X-Rays Using Deep Learning

pyi10@jhmi.edu

PURPOSE

To develop and test the performance of deep convolutional neural networks (DCNNs) for the automated detection of 1) age and 2) gender on chest radiographs (CXRs).

METHOD AND MATERIALS

We obtained 112,120 frontal CXRs from the NIH ChestX-ray14 database performed in 48,780 females (44%) and 63,340 males (56%) ranging from 1 to 95 years old; amongst 5941 pediatric CXRs (5%), 2546 (43%) were female (p=0.3). The entire dataset was split into training (70%), validation (10%), and test (20%) datasets and used to train, validate, and test the ResNet-18 DCNN pretrained on ImageNet for: 1) determination of gender (using both entire dataset and only pediatric CXRs); 2) determination of age <18 years old or >=18 years old (using entire dataset); and 3) determination of age <11 years old or 11-18 years old (using only pediatric CXRs). During each training epoch, each image was augmented via random rotations, cropping, and flipping. We also tested the DCNNs on an external dataset of 662 CXRs performed in adults and children from China. Receiver operating characteristic (ROC) curves with area under the curve (AUC) and standard diagnostic measures (e.g, accuracy) were used to evaluate DCNN test performance with AUCs statistically compared between DCNNs.

RESULTS

The DCNNs trained to determine gender on the entire dataset and pediatric CXRs only had AUC of 1.0 and 0.91, respectively (p<0.0001) and accuracy of 98% and 83%, respectively. The DCNNs trained to determine age <18 years old or >=18 years old and <11 years old or 11-18 years old had AUCs of 0.99 and 0.96 (p<0.0001), respectively, with accuracy of 98% and 89%, respectively. On the external dataset, the DCNNs achieved AUC of 0.98 for gender (p=0.01) and 0.91 for determining age < or >=18 years old (p<0.001), with accuracy of 94% and 97%, respectively.

CONCLUSION

DCNNs can accurately predict gender from CXRs, as well as distinguish between adult and pediatric patients, in both American and Chinese populations, and between pre-pubescent and pubescent children in American populations. The ability to glean demographic information from CXRs may aid forensic investigations, as well as help identify novel anatomic landmarks for gender and age.

CLINICAL RELEVANCE/APPLICATION

Deep convolutional neural networks can accurately infer gender and age from chest radiographs from American and Chinese populations, which may be a useful tool in "forensic" radiology.

mbaikpour@mgh.harvard.edu

PURPOSE

To determine the value of portal vein pulsatility for diagnosis of high risk nonalcoholic steatohepatitis (NASH).

METHOD AND MATERIALS

This IRB-approved HIPAA-compliant study included 123 consecutive subjects (54 males and 69 females, average age of 50.3±12.2 years) with a biopsy proven diagnosis of Nonalcoholic Fatty Liver Disease (NAFLD) who had undergone Duplex Doppler ultrasound assessment of their main portal vein within 1 year prior or after their liver biopsy, from January 2014 to February 2018. We reviewed the Doppler ultrasound images of these patients, used the spectral waveform to measure the maximum (Vmax) and minimum (Vmin) velocity of blood in their portal veins, and calculated the Venous Pulsatility Index (VPI) defined as (Vmax-Vmin)/Vmax. Area under the receiver operating characteristic curve (AUC) was measured to determine the value of this index for diagnosis of high risk NASH (hrNASH), which is defined as a NASH stage of equal or greater than F2 based on the extent of fibrosis on liver biopsy.

RESULTS

Of 123 study subjects, 33 (26.8%) had hrNASH. These patients had a significantly lower VPI than the other 90 subjects (0.19±0.08 vs. 0.32±0.11; $p<0.001$). The AUC of VPI for diagnosis of hrNASH was calculated to be 0.838 (95%CI: 0.757-0.920). Subgroup analysis in subjects whose Doppler ultrasound assessment was performed within 6 months of liver biopsy yielded a similar hrNASH diagnosis AUC of 0.830 (95%CI: 0.735-0.925). VPI analysis was demonstrated to be superior to commonly used hrNASH diagnosis serum tests in this cohort.

CONCLUSION

VPI analysis may be a useful non-invasive tool for hrNASH diagnosis.

CLINICAL RELEVANCE/APPLICATION

VPI analysis may be useful for high risk NASH diagnosis, which is important for liver-specific mortality NAFLD risk assessment.

SSE07-03 Viscoelasticity Measurement Using Shear Wave Elastography for the Evaluation of Allograft Rejection after Liver Transplantation

Monday, Nov. 26 3:20PM - 3:30PM Room: S402AB

dhlee.rad@gmail.com

PURPOSE

To evaluate whether viscoelasticity measurement using shear wave elastography could help detect acute cellular rejection of allograft after liver transplantation

METHOD AND MATERIALS

Between Jan 2018 and March 2018, we prospectively enrolled 33 patients who underwent liver transplantation. Ultrasound (US) examination of allograft liver using shear wave elastography was done for all of 33 patients, and stiffness value (kilopascal, kPa) as well as shear wave dispersion slope ([m/s]/kHz) of allograft liver were measured and recorded. Percutaneous liver biopsy was performed to diagnose acute cellular rejection histopathologically using 18G automating cutting needle immediate after US evaluation. Relationship between US parameters obtained from shear wave elastography and presence of acute cellular rejection on histopathologic examination was evaluated using Mann-Whitney U test and receiver operating characteristic analysis.

RESULTS

Allograft liver stiffness value as well as shear wave dispersion slope were successfully measured in all of 33 patients. Acute cellular rejection was diagnosed in 12 patients out of 33 patients (12/33, 36.4%) on histopathologic examination. Mean allograft liver stiffness value was 8.04 ± 2.33 kPa in 12 patients with acute cellular rejection, and was not significantly different from that of 7.07 ± 3.62 kPa in 21 patients without acute cellular rejection (P=0.082). However, mean shear wave dispersion slope of allograft liver was 15.03 ± 2.85 [m/s]/kHz in 12 patients with acute cellular rejection, and significantly higher than that of 11.81 ± 4.10 [m/s]/kHz in 21 patients without (P=0.004). The area under the curve for the prediction of acute cellular rejection in allograft liver was 0.802 (P<0.001, 95% confidence interval; 0.626-0.919) for shear wave dispersion slope with a sensitivity of 100% (12/12) and specificity of 57.1% (12/21) when the cut-off value was set at 11.5 [m/s]/kHz.

CONCLUSION

Shear wave dispersion slope obtained from shear wave elastography could have a potential to predict the presence of acute cellular rejection in allograft liver after transplantation, and could help make decision regarding the treatment plan for liver transplantation recipients.

CLINICAL RELEVANCE/APPLICATION

Shear wave dispersion slope obtained from shear wave elastography could help make decision regarding the treatment plan for liver transplantation recipients.

SSE07-04 Role of Contrast-Enhanced Ultrasound for the Post-Treatment Evaluation of Hepatocellular Carcinoma

PURPOSE

Minimally-invasive treatments for hepatocellular carcinoma (HCC) continue to rise in popularity. Monitoring treated lesions for residual tumor has been accomplished by contrast-enhanced CT or MR (CEMR); however, there is growing interest in the use of contrast-enhanced ultrasound (CEUS) to monitor treatment response following thermo-ablation and embolization of hepatocellular carcinoma. We sought to compare post-treatment findings at CEUS with findings at CEMR to evaluate the efficacy of monitoring treatment response with CEUS.

METHOD AND MATERIALS

We reviewed CEUS examinations performed for evaluation of hepatomas treated by thermo-ablation and/or embolization from April 2017 through March 2018. A positive CEUS or CEMR was defined as residual enhancing tumor within the treatment bed. CEUS examinations were compared with CEMR after treatment but before any further intervention on that lesion.

RESULTS

We identified 28 lesions in 24 patients that underwent CEUS for post-treatment evaluation. 22 lesions (79%) had CEMR for comparison. Mean time between CEMR and CEUS was 37.8 days (range: 0-112 d). CEUS identified enhancing tumor in 86.7% (13/15) lesions with positive CEMR, and did not demonstrate enhancement in any of 100% (5/5) of lesions with negative CEMR. While CEUS did not detect any CEMR-occult disease, it did confirm presence of enhancing tumor in 2 lesions with indeterminate CEMR. Finally, CEUS confirmed absence of tumor in a lesion characterized as negative at noncontrast MR, but which could not be confirmed by CEMR due to contraindication to gadolinium. Overall, CEUS had a 90% (18/20) agreement rate with diagnostically confirmed lesions on CEMR.

CONCLUSION

CEUS demonstrated high agreement rate with CEMR in our study population of ablated and embolized hepatic lesions. There were several cases for which contrast-enhanced ultrasound outperformed MRI or enabled evaluation in patients who could not undergo contrast-enhanced MR. These results suggest an ongoing role for CEUS as an adjunct to cross-sectional imaging in the monitoring of HCC following ablation or embolization.

CLINICAL RELEVANCE/APPLICATION

Contrast-enhanced ultrasound may potentially add value in the evaluation of treated hepatic lesions, particularly in patients with contraindications to contrast-enhanced MR or in whom MRI findings are inconclusive.

SSE07-05 A Comparative Study of Shear Wave Elastography Measurement on Liver's Right Lobe and Left Lobe for diagnosis of Chronic Liver Disease using Liver Biopsy as 'Gold Standard'

Monday, Nov. 26 3:40PM - 3:50PM Room: S402AB

ath.angelakis@gmail.com

PURPOSE

Chronic Liver Disease (CLD) is one of the major causes of death nowadays and the major cause of Hepatocellular Carcinoma development. Therefore, accurate diagnosis regarding CLD progress is very important. Although Liver Biopsy (LB) is considered as 'Gold Standard' for diagnosis, several non-invasive methods have emerged in order to avoid LB complications. Standard SWE examination protocol involves measurements on the Right Lobe (RL), but this is not always feasible since on CLD we observe liver's RL shrinkage and liver's Left Lobe (LL) widening. On the other hand, an alternative measurement on LL can be performed but has not been yet evaluated. The aim of this study is to compare the performance of SWE on liver's RL and LL in CLD diagnosis using LB as 'Gold Standard'.

METHOD AND MATERIALS

163 subjects, 56 normal (F0) and 107 with CLD (F1-F4), were included in the study. a B-Mode and Color/Power Doppler examination was performed on each patient. SWE measurements were performed on the RL and LL of each patient. SWE measurements on each lobe were compared to LB results that were classified according to the Metavir Classification System for fibrosis (F0-F4). Receiver Operating Characteristic analysis was then performed on each set of SWE measurements (RL and LL) to obtain best cut-off stiffness values.

RESULTS

ROC analysis was performed for each lobe (RL/LL) showing: AccuracyRL/AccuracyLL = 0.9448/0.9264 for F=F4, AccuracyRL/AccuracyLL = 0.9448/0.9509 for F>=F3, AccuracyRL/AccuracyLL = 0.9571/0.9387 for F>=F2, and AccuracyRL/AccuracyLL = 0.8589 /0.8957 for F>=F1. Best cut-off stiffness values calculated for each lobe (RL/LL) compared to Metavir fibrosis stages were: F=F4: 11.8/10.6 kPa, F>=F3: 9.7/9.8 kPa, F>=F2: 8.3/8.1 kPa, F>=F1: 6.3/5.9 kPa respectively.

CONCLUSION

This study shows that SWE measurements on the LL, when feasible, are reliable in CLD diagnosis and can be used alternatively when measurements on the RL are not possible.

CLINICAL RELEVANCE/APPLICATION

This study shows that SWE measurements on the LL, when feasible, are reliable in CLD diagnosis and can be used alternatively when measurements on the RL are not possible.

SSE07-06 SHI CEUS Signals in the Hepatic Vein are an Indirect Sign of Pathophysiology Changes Caused by Portal Hypertension

PURPOSE

To determine if the presence of SHI signals inside the hepatic vein can be used as an indirect qualitative sign of portal hypertension.

METHOD AND MATERIALS

Eighty-seven patients that were part of an IRB and FDA approved portal hypertension study underwent a subharmonic imaging (SHI) contrast US (CEUS) examination of their portal and hepatic veins using a modified Logiq 9 scanner (GE, Milwaukee, WI) with a 4C probe. SHI is a new CEUS imaging technique where the receive frequency is half of the fundamental (1.25 and 2.5 MHz, respectively) resulting in better tissue suppression. Images were acquired after infusion of the US contrast agent Sonazoid (GE Healthcare, Oslo, Norway) at a rate of 1.44μL of microbubbles/kg/hour and analyzed for the presence or absence of SHI signals in the hepatic vein; based on the assumption that in portal hypertensive patients SHI signals would be seen in the hepatic vein. These findings were compared to the hepatic venous pressure gradient (HVPG; i.e., the gold standard) obtained by transjugular liver biopsy as part of the subject's standard of care.

RESULTS

Out of the 87 cases, 10 cases were excluded, 5 cases because the HVPG values were clinically discordant and 5 cases because the ROI used was close to the IVC junction causing the physiologic reflux from the IVC to not permit a clear evaluation of the hepatic vein SHI signal. From the 77 patients that could have their data analyzed, 44 had increased HVPG values corresponding to subclinical and clinical portal hypertension (>5 and 10 mmHg, respectively) and 33 patients had normal HVPG values (< 5mmHg). Qualitative assessments of the digital clips acquired during the examinations showed that in all of the 44 cases with increased HVPG values a SHI signal was seen in the hepatic vein and from the 33 cases with normal HVPG values, 30 cases had no SHI signal in the hepatic vein. The overall accuracy was 96% (74/77) with a sensitivity of 100% (44/44) and specificity of 91% (30/33).

CONCLUSION

The presence of SHI signal inside the hepatic vein can be used as a qualitative indirect sign for portal hypertension.

CLINICAL RELEVANCE/APPLICATION

SHI CEUS evaluation of the hepatic vein is a non-invasive and safe method that can be used in as a new initial, qualitative sign of portal hypertension.

PURPOSE

To describe 2018 international current practices in imaging-based surveillance, diagnosis, staging, and treatment response assessment for hepatocellular carcinoma (HCC).

METHOD AND MATERIALS

Institutional review board exemption was granted for this survey-based study. An electronic survey was sent to members of the LI-RADS International Working Group (94 liver imaging experts from 27 countries and 5 continents) and 40 additional abdominal radiologists identified by survey authors. The 42-item survey captured data on respondents' demographics and liver imaging expertise; local imaging practices for HCC screening, surveillance, diagnosis, staging, and treatment response assessment; and personal use of HCC diagnostic imaging systems.

RESULTS

Of 90 respondents (response rate, 55%), 21% were from Asia, 31% from Europe, 8% from North America, 36% from South America, and 4% from Australasia. Similar proportions of respondents were in academic (47%) and private or mixed practice (53%). Median respondents' experience was 16 years (interquartile range, 8-24 years). Noncontrast ultrasound was the most common modality for HCC screening and surveillance (89%). Multiphase computed tomography and MRI were used for HCC diagnosis by 96% and 83% of respondents, respectively. Biopsy was most commonly performed for lesions considered probably or definitely malignant but not meeting definitive HCC imaging criteria for HCC (89%). Extracellular contrast agents (72%) were the most commonly used MRI contrast agents and Lumason™/SonoVue™ (64%) the most commonly used CEUS contrast agent. A majority (95%) of respondents use ancillary in addition to major imaging features for liver lesions assessment. The use of HCC diagnostic imaging systems for HCC varied by region. Response Evaluation Criteria In Solid Tumors (RECIST) or mRECIST were most the common criteria for assessing HCC treatment response (53%). Usage of diagnostic systems varied from 0-81% depending on the system and region. Overall, the

most commonly used diagnostic systems were LI-RADS (64%), AASLD (33%), and EASL-EORTC (30%).

CONCLUSION

HCC imaging diagnostic systems vary geographically. Efforts to unify these diagnostic systems should rely on larger surveys to identify and address regional differences and potential barriers to adoption.

CLINICAL RELEVANCE/APPLICATION

Regional differences in imaging practices should be taken into account in developing a unified system for imaging of HCC.

SSE08-02 Add the Value of Gd-EOB-DTPA-Enhanced MRI in Characterizing Cirrhotic Nodules with Atypical Enhancement on CT Enhanced Images: Implications for CT/MRI LI-RADS V2017 Characterization of Hepatocellular Carcinoma

Monday, Nov. 26 3:10PM - 3:20PM Room: S404AB

Participants
Jinkui Li, Lanzhou, China (*Presenter*) Nothing to Disclose
Junqiang Lei, Lanzhou, China (*Abstract Co-Author*) Nothing to Disclose
Zhao Liu, Lanzhou, China (*Abstract Co-Author*) Nothing to Disclose
Yongsheng Xu, Lanzhou, China (*Abstract Co-Author*) Nothing to Disclose
Hai-Feng Liu II, Lanzhou, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the value of Gd-EOB-DTPA-enhanced magnetic resonance imaging (MRI) in characterizing atypically enhanced nodules in high-risk patients detected on CT enhanced images for the detection of hepatocellular carcinoma (HCC) in reference to the CT/MRI LI-RADS v2017 classification system.

METHOD AND MATERIALS

Data of 43 patients consecutive patients with 50 atypical nodules seen on enhanced CT images who further underwent Gd-EOB-DTPA MRI between January 2016 and June 2017 were retrospectively analyzed. CT and MRI examination interval were range 1 to 52 days. Two experienced radiologist assigned LI-RADS scores with a blind method. The diagnostic accuracy of CT/MRI LI-RADS v2017 was assessed by comparing with pathological or clinical diagnosis, which as s reference standard.

RESULTS

Excellent agreement between readers were reached with CT ($K=0.806$, $P<0.001$) and MRI ($K=0.852$, $P<0.001$) , respectively. MRI can show more major and ancillary features than CT significantly ($P<0.05$). With LR-4, LR-5 regarded as HCC, the accuracy of CT and MRI in diagnosing HCC by comparing with the reference standard was 86.67% and 90.9%, respectively. There is no significant differences in statistic ($P>0.05$). However, 17 HCC lesions categorized as LR-3 with CT were classified as LR-4 or LR-5 with MRI, and 1 benign lesion was classified as LR-3 with CT and LR-2 with MRI.

CONCLUSION

With LI-RADS, Gd-EOB-DTPA MRI is more sensitive than CT for diagnosing HCC by providing more information. Thus, Gd-EOB-DTPA MRI can improve the accuracy for detecting HCC of atypical enhanced nodules on CT.

CLINICAL RELEVANCE/APPLICATION

Gd-EOB-DTPA MRI can improve the accuracy for detecting HCC of atypical enhanced nodules on CT with LI-RADS.

SSE08-03 Impact on Liver Imaging Reporting and Data System Categorization and Tumor Staging of the 2018 Change in the American Association for the Study of Liver Diseases Criteria for HCC

PURPOSE

The American Association for the Study of Liver Diseases (AASLD) in 2018 changed one of its criteria for the diagnosis of hepatocellular carcinoma (HCC). Previously, the AASLD counted 10-19 mm observations with arterial phase hyperenhancement (APHE) and "washout" (WO) as HCC only if they were visible at antecedent surveillance ultrasound (US). The latest AASLD guidance removed the requirement for US visibility so that all 10-19 mm observations with APHE and WO would count as HCC, regardless of US visibility. The aim of this study is to determine the impact on LI-RADS categorization and HCC staging if LI-RADS adopts the new AASLD criterion, causing a subset of LR-4 observations to be recategorized LR-5.

METHOD AND MATERIALS

All MRI and CT reports issued using a standardized LI-RADS template at one tertiary care center between 4/15-3/18 were identified. For each reported LR-3, LR-4, or LR-5 observation, the presence of each major feature (size, APHE, WO, 'capsule', threshold growth [TG]) and antecedent US visibility was extracted from the reports retrospectively. All observations were assigned a LI-RADS v2017 category based on the extracted features. Observations categorized LR-4 using v2017 were then recategorized by adopting the new AASLD criterion (modified LI-RADS). Patients were assigned a radiologic tumor stage (T-stage) based on the number and size of observations categorized LR-5, first using v2017 LI-RADS and then using modified LI-RADS.

RESULTS

Of the 672 reported observations in 411 patients reviewed for this study, 187 observations (28%) in 149 patients were categorized LR-4 using v2017 LI-RADS (median size 13 mm, IQR 10-19 mm). Of 187 LR-4 observations, 78 (42%) had APHE and WO only, without US visibility, 'capsule', or TG; these were re-categorized LR-5 using modified LI-RADS. 57 of 67 (85%) patients with re-categorized observations had a change in radiologic T-stage: 68% (39/57) from stage 0 to 1, 12% (7/57) from stage 0 to 2, 5% (3/57) from stage 1 to 2, 12% (7/57) from stage 2 to 3, and 2% (1/57) from stage 2 to 4a.

CONCLUSION

The proposed AASLD guideline change will cause 42% of LR-4 observations to be categorized LR-5 and 85% of affected patients to have an increase in radiologic T-stage.

CLINICAL RELEVANCE/APPLICATION

The revised AASLD criteria will cause substantial upgrading of observation and upstaging of patients; further studies are needed to assess how these changes affect accuracy and outcome.

SSE08-04 Comparison of Diagnostic Performance of Non-Contrast MRI and Abbreviated MRI in Initially Diagnosed Hepatocellular Carcinoma Patients: A Simulation Study of Surveillance for Hepatocellular Carcinomas

dumkycji@gmail.com

PURPOSE

To compare the diagnostic performance of non-contrast MRI and abbreviated MRI using gadoxetic acid for detecting hepatocellular carcinoma (HCC) in initially diagnosed, early stage HCC patients

METHOD AND MATERIALS

We identified 142 consecutive, initially diagnosed HCC patients within Milan criteria, who performed liver MRI between 2015 and 2016. For the control group, we enrolled 158 consecutive patients without HCC but had risk factors (liver cirrhosis, chronic hepatitis B or C) of HCC, who also performed liver MRI in the same period. Total number of HCCs was 177 and the number of HCCs smaller than 2 cm and 2 cm <= were 92 and 85, respectively. Two radiologists independently reviewed two MRI sets; non-contrast set and abbreviated set. Non-contrast set consists of T2 FSE/ssFSE with fat saturation, T1 in- and out-of-phase image, non-contrast 3D GRE T1 images, DWI (with b-value 500s/mm2) and ADC map. Abbreviated set consists of T2 FSE/ssFSE with fat saturation, 3D GRE T1 images at hepatobiliary phase 20 minutes after gadoxetic acid injection, DWI and ADC map. Both readers recorded the presence, size and location of HCCs.

RESULTS

In per-patient analysis, sensitivity of reader 1 of non-contrast and abbreviated set were 90.8% and 89.8%, respectively. Specificity of non-contrast and abbreviated set were 92.7% and 92.3%, respectively. For reader 2, sensitivity of both sets were 87.4% and 87.5%, and specificity were 90.3% and 91.7%, respectively. When comparing two image sets, there was no statistical difference in both readers (p=0.65 and 0.86 for reader 1 and 2, respectively, using MeNemar test). Kappa statistics showed excellent inter-observer agreement (0.86 for non-contrast and 0.84 for abbreviated set). In per-tumor analyses, sensitivity of reader 1 for non-contrast and abbreviated set were 81.9% and 83.1%, respectively. For reader 2, per-tumor sensitivity for both sets were 80.8% and 83.6%, respectively.

CONCLUSION

Non-contrast and abbreviated MRI using gadoxetic acid showed comparable diagnosing performance for detecting HCCs in early stage HCC patients.

CLINICAL RELEVANCE/APPLICATION

Ultrasonography is not sensitive enough for the surveillance of patients with very high risk of HCCs. Non-contrast MRI is cheaper

than abbreviated MRI using gadoxetic acid and can avoid the repeated usage of contrast media which can be accumulated in human brain. Non-contrast liver MRI can be a potential candidate for a surveillance tool of HCC.

SSE08-05 CT Findings on Hepatocellular Carcinoma in Patients with Hepatitis C Showing a Sustained Virologic Response after Interferon-Free Therapy: Comparison with that in Patients with Interferon-Based Therapy

PURPOSE

Hepatitis-C virus (HCV) infection is a common cause of chronic hepatitis and can lead to hepatocarcinogenesis. Antiviral therapy with interferon (IFN) can reduce the incidence of hepatocarcinogenesis especially in patients with a sustained virologic response (SVR). New direct-acting antiviral agents (DAA), approved in several countries for the treatment of chronic HCV infection, have markedly increased the SVR rate. However, it remains controversial whether IFN-free therapy such as DAA reduces hepatocarcinogenesis as same as IFN-based therapy. We compared the CT findings of hepatocellular carcinoma (HCC) in patients with HCV infection who manifested SVR after IFN-free and IFN-based therapy.

METHOD AND MATERIALS

We divided 43 patients with surgically resected solitary HCC that developed after achieving SVR for HCV infection into 2 groups. Group A (n=30) had received IFN-based- and group B (n=13) IFN-free therapy. We compared the patient- and the HCC characteristics (size and histological grade), serum tumor markers, and the tumor-liver contrast (TLC: difference in the CT value between the hepatic parenchyma and HCC) on arterial- and equilibrium-phase at dynamic CT scans between two groups using the Fisher exact- and the Mann-Whitney's U test.

RESULTS

There were no significant inter-group differences with respect to the patient- and the HCC characteristics and serum tumor markers. In the equilibrium phase, TLC was significantly higher in group B than group A (median 16.1 vs 9.2 Hounsfield units, $p<0.01$). In the arterial phase there was no significant difference in TLC between the two groups ($p=0.17$).

CONCLUSION

The CT features of HCC in patients who achieved SVR after treatment with IFN-free or IFN-based therapy were different.

CLINICAL RELEVANCE/APPLICATION

Differences in the CT imaging features of HCC that developed after achieving SVR in patients treated with IFN-based- or IFN-free therapy may suggest differences in the biological characteristics of their tumors.

SSE08-06 Negative Results at US-Guided Biopsy of Focal Liver Lesions: Conservative or Aggressive Management?

PURPOSE

In patients with suspicious malignant liver lesions, the management of a negative result at biopsy is challenging. Our purpose was to investigate patient- and procedure-related variables affecting the false-negative (FN) results of US-guided biopsy of focal liver lesions, and to develop a patient-specific predictive model for the management of negative biopsy results.

METHOD AND MATERIALS

In this retrospective IRB-approved, HIPAA-compliant study, we included 389 patients (mean age 62 years ± 12.1; 175 men, 214 women) who had undergone US-guided liver biopsy of suspicious malignant liver lesions between 2013-2015. A total of 405 lesions (mean diameter: 3.8 cm ±2.7) were analyzed. We collected multiple patient- and procedure- related variables, including gender, age, body mass index, history of malignancy, cirrhosis, lesion size and location and sample acquisition technique. By comparing pathology reports of biopsy and the reference standard (further histology or imaging follow-up>1 year), the results were categorized as true-positive (TP), true negative (TN), and FN. Diagnostic accuracy and diagnostic yield were measured. Univariate and multivariate analysis was performed to evaluate variables affecting FN results. Statistical significance was set at $p<0.05$. A

patient-specific predictive model of FN results based on decision tree was fit.

RESULTS

Diagnostic accuracy and diagnostic yield of US-guided liver biopsy were 93.8% (380 of 405) and 89.4% (362 of 405), respectively. The FN rate was 6.5% (25 of 387). Predictive variable of a FN result at univariate analysis included body mass index, lesion size and sample acquisition technique. The only independent predictors at multivariate analysis was patient age. By taking into account lesion size and location in combination with patient age and history of previous malignancy, we developed a decision tree model predictive of FN results with confidence up to 100%.

CONCLUSION

FN results are rare but not negligible at US-guided liver biopsy. Independent predictors of FN results are difficult to identify. Our decision tree predictive model suggests that patient age, history of malignancy, lesion size and location may predict FN results with high confidence.

CLINICAL RELEVANCE/APPLICATION

We developed a decision tree predictive model that allows to identify US-guided liver biopsy results with high probability of being false-negative, and thus could support personalized management.

zhuyj04@126.com

PURPOSE

To investigate the value of contrast enhanced MR imaging (CE-MRI) texture analysis in preoperative predicting the microvascular invasion (MVI) status of hepatocellular carcinoma (HCC).

METHOD AND MATERIALS

A retrospective study of 142 pathologically confirmed cases were conducted. Studies were divided into two cohort: the training cohort (n=99) and validation cohort (n=43), including MVI positive group (n=53) and MVI negative group (n=89) based on pathology. 58 textural parameters were extracted in two cohort using baseline MRI on both arterial phase (AP) and portal phase (PP) by a 3D method. The clinical-radiological features were also included. Univariate logistic regression identified potentially predictive parameters, which were entered into the multivariate logistic regression to build the texture model and the combined model together with clinical features to predict development of MVI.

RESULTS

In the clinical features, significant difference was found in max tumor diameter (MTD) (P=0.002), tumor differentiation (P=0.026) and AFP (P=0.025) between the two groups in training cohort. Four MR texture features in AP and five in PP were used to build the texture model. The combined model in AP showed a better diagnostic performance than PP using ROC analysis in validation cohort, with area under the curve (AUC) 0.794 vs. 0.706, sensitivity 0.812 vs. 0.750 and specificity 0.852 vs. 0.704.

CONCLUSION

The CE-MRI 3D texture analysis can predict MVI of HCC preoperatively and noninvasively, and AP image showed better predictive efficiency than in PP image. Combined model with clinical-radiological features could improve MVI prediction ability to some extent.

CLINICAL RELEVANCE/APPLICATION

Preliminary studies had shown that MVI was a risk factor for the overall survival and recurrence rates of HCC patients. However, there was no accepted method for predicting MVI preoperativeIn this study, 3D CE-MRI texture analysis was used together with clinical-radiological features to build model to predict the MVI status in a training cohort preoperatively. A validation cohort was set to validating the model efficiency and stability. After multivariate logistic regression, our result revealed that the combined model in arterial phase showed a good performance to predicting MVI with AUC of 0.810. This is of great clinical significance for the surgical decision-making and treatment after surgery to avoid recurrence.

SSE09-02 Machine Learning Models for Prediction of Hepatocellular Carcinoma Response to Transcatheter Arterial Chemoembolization based on Baseline CT Image Texture Analysis and clinical Staging Data

KMElsayes@mdanderson.org

PURPOSE

The purpose of this work is to develop a fully automated algorithm that uses pre-therapeutic quantitative image features and clinical data as inputs to predict HCC response to TACE.

METHOD AND MATERIALS

TACE outcome information on 113 HCCs in 105 patients receiving first-line treatment with TACE was obtained from a database. An automated segmentation program was developed using fully convolutional neural networks and random forest classification methods to parse out each HCC. The Dice similarity coefficient was calculated to compare the automated segmentation accuracy with that of a manually validated process. A boruta feature selection algorithm was used for data reduction for the quantitative image features considered. The response of HCC to TACE was predicted using a second random forest classifier with the inputs; 1) Barcelona clinic liver cancer (BCLC) stage alone 2) quantitative image features alone 3) BCLC stage plus quantitative image features. The primary clinical endpoint was time to progression (TTP) based on follow-up CT radiological criteria (mRECIST). TTP cutoff of 14 weeks was used to stratify patients as follows; TTP >= 14 wks as TACE susceptible and would benefit from further TACE sessions, TTP < 14 wks as TACE refractory and would be better suited for a change of treatment strategy.

RESULTS

The automated segmentation model had a Dice similarity coefficient scores at baseline of 0.65 ±0.048 and 0.64 ±0.081 for viable and necrotic tissue, respectively. The model's response prediction accuracy rate was 73.2% using a combination of the BCLC stage and quantitative image features (P-value= 0.0096, 95% CI=0.64-0.8, SN=0.83, SP=0.55) versus 62.9% using the BCLC stage alone. Shape image features of the viable, necrotic and background liver were the dominant features correlated to the TTP as selected by the Boruta method and were used to predict the outcome.

CONCLUSION

This preliminary study demonstrates the feasibility of improving the accuracy of predicting treatment response of HCC to TACE therapy using quantitative imaging feature obtained prior to therapy. The approach is likely to provide useful information for assisting in patient selection for the continuation of TACE therapy versus changing treatment strategy.

CLINICAL RELEVANCE/APPLICATION

TACE is recommended for unresectable BCLC stage B HCC. Tumor response to first TACE session affects the treatment strategy.

SSE09-03 CT-Textural Analysis for Discrimination Between Chronic Lymphocytic Leukemia (CLL) and CLL Transformed into Diffuse Large B-Cell Lymphoma (Richter's Syndrome)

Monday, Nov. 26 3:20PM - 3:30PM Room: S404CD

For information about this presentation, contact:

Christian.Reinert@med.uni-tuebingen.de

PURPOSE

To find CT-texture analysis (CTTA) features for discrimination between chronic lymphocytic leukemia (CLL) including indolent and aggressive subtypes and diffuse large B cell lymphoma (DLBCL) caused by transformation (Richter's syndrome).

METHOD AND MATERIALS

We retrospectively identified 52 patients with indolent (26/52) or aggressive CLL (8/52) and DLBCL caused by Richter's syndrome (18/52) who underwent contrast-enhanced CT (CECT) between 03/2011 and 05/2017 using a standardized protocol (120 kV, 200-250 mAs, thin-collimation, weight-adapted i.v. contrast media in portal-venous phase). ROIs were set in the main lymphoma masses as large as possible avoiding partial volume averaging. CTTA evaluation included heterogeneity, intensity, average, deviation, skewness, entropy of co-occurrence matrix, number non-uniformity grey-level dependence matrix (NGLDM), mean contrast neighborhood grey-tone difference matrix (NGTDM) and entropy NGLDM. For each CTTA parameter the respective mean, entropy and uniformity were calculated. For final calculation a medium filter was used. We first grouped all CLLs and compared them with DLBCL and secondly compared both the indolent and aggressive CLL subtypes separately with DLBCL.

RESULTS

CTTA-values between the entire CLL-group and DLBCL significantly differed with respect to entropy (P<.002), uniformity of heterogeneity (P<.008), mean intensity (P<.0001), mean average (P<.007), entropy of co-occurrence matrix (P<.012) and number

non-uniformity (P<.03). Indolent CLLs significantly differed from DLBCL in terms of entropy (P<.007), uniformity of heterogeneity (P<.018), mean intensity (P<.001), mean average (P<.004) whereas aggressive CLLs were significantly different from DLBCL in terms of entropy (P<.03), uniformity of heterogeneity (P<.02), mean intensity (P<.02) and mean entropy of co-occurrence matrix (P<.04).

CONCLUSION

CTTA features significantly differ in subjects with CLL compared to DLBCL caused by Richter's syndrome and could therefore be implemented in the routine evaluation of patients suspected of CLL transformation into a DLBCL. Differences in CTTA-features represent ultrastructural characteristics like tissue heterogeneity and contrast-induced attenuation.

CLINICAL RELEVANCE/APPLICATION

Differentiation between CLL and DLBCL caused by Richter's syndrome has major therapeutic and prognostic implications.

SSE09-04 Correlation Between Whole-Tumor CT Texture Analysis and Pathological Findings in Resected Primary Colon Cancer: Preliminary Results

Monday, Nov. 26 3:30PM - 3:40PM Room: S404CD

fabio.lombardo@me.com

PURPOSE

to correlate tumor heterogeneity by using whole-tumor CT texture analysis with pathological findings in primary colon cancer.

METHOD AND MATERIALS

IRB-approved retrospective study; need for informed consent was waived. Thirty patients with resected primary colon cancer were included (21M, 9F; mean age 75y). Thirty-nine first, second and higher order texture features were obtained from preoperative CT portal-venous phase images using a dedicated software (LifEX, www.lifexsoft.org). The results were compared with 10 histopathological features from the specimen (histology, tumor grade, growth pattern, T status, N status, presence of ulceration, percentage of necrosis, presence of vascular and lymphatic invasion, presence of free nodules).

RESULTS

tumor histology, tumor grade, growth pattern, T and N status were significantly correlated with 20 different Grey-Level Co-occurrence Matrix (GLCM), Grey-Level Run-Length Matrix (GLRLM), Grey-Level Zone-Length Matrix (GLZLM) and Neighborhood Grey-Level Different Matrix (NGLDM) parameters (Mann-Whitney test; p<0.05). No differences were found between first order texture features and the considered pathological findings (p=ns).

CONCLUSION

CT second and higher order texture features correlate with tumor biology and with T/N status at pathology.

CLINICAL RELEVANCE/APPLICATION

Second and higher order texture features are a new promising tool for preoperative characterization of colon cancer.

SSE09-05 Performance of 3T-MRI-Derived Texture Analysis in Rectal Cancer: Predicting Tumoral Response to Therapy

marta.zerunian@gmail.com

PURPOSE

To determine the performance of texture analysis(TA) in predicting tumoral response to therapy in patients with rectal cancer.

METHOD AND MATERIALS

Forty consecutive patients with clinical suspicion of rectal cancer were prospectively enrolled and had undergone 3T-MRI examination pre- and post- chemo-radiotherapy(CRT). All patients underwent total mesorectal excision 6-8 weeks after the end of CRT. The gross specimens were analyzed by an expert gastrointestinal pathologist and the histological results were considered the reference standard. A region-of-interest was manually drawn around the largest tumour area on a single axial oblique T2-w slice. Slices were analyzed with a dedicated software(TextRad) and the following first order statistical TA parameters were computed: Skewness, Kurtosis, Entropy, and Mean Value of Positive Pixels[MPP]). Non-parametric Mann-Whitney U test was used to compare

TA parameters and the response rate among complete responders(CR), partial responders(PR), and non-responders(NR) before and after CRT. Receiver operating characteristic curves(ROC) were used to assess the discriminatory power of TA parameters to predict complete response to CRT.

RESULTS

Thirteen patients(32,5%) showed CR, twenty-two patients(55%) showed PR and five patients(12,5%) were classified as NR. After CRT, CR showed significant reduction of Entropy(6.17 ± 0.54 vs 6.49 ± 0.43), Kurtosis(0.72 ± 1.05 vs 2.60 ± 2.01) and MPP(306.33 ± 168.97 vs 414.24 ± 219.26); all P <= 0.002. After CRT, PR/NR showed significant reduction of Entropy(6.47 ± 0.57 vs 6.70± 0.50) and Skewness(0.53 ± 0.75 vs 0.35 ± 0.67); all P <= 0.029 . After CRT, CR showed significant lower Kurtosis(0.33 ± 0.65) and MPP(262.19 ± 135.28), compared to PR/NR(Kurtosis: 1.87 ± 1.85; MPP: 357.54 ± 155.07); all P <= 0.042.Entropy was the only TA parameter showing significance in the predicting CR(AUC 0.64 [95% CI: 0.57 - 0.71]), P < 0.001 with the best cut-off value of >= 6.68, with a sensitivity of 76.9% and a specificity of 38.46% in predicting CR.

CONCLUSION

Among TA parameters Entropy might be a good predictor of tumor response showing the best AUC in ROC curves with good sensitivity and specificity. Kurtosis and MPP showed a significant decrease in patients with CR.

CLINICAL RELEVANCE/APPLICATION

TA parameters derived from T2 images such as Kurtosis, Skewness and Entropy might potentially play an important role as imaging biomarkers of tumoral response to CRT in patients with rectal cancer.

SSE09-06 Texture Analysis of Pancreas MRI: Utility for Differentiating Pancreatic Head Cancer from Mass-Forming Chronic Pancreatitis at the Pancreatic Head

Monday, Nov. 26 3:50PM - 4:00PM Room: S404CD

Participants
Lei Chu, MSc, Chengdu, China (*Presenter*) Nothing to Disclose
Rongbo Liu, MD, Sichuan, China (*Abstract Co-Author*) Nothing to Disclose
Xin Li, Shanghai, China (*Abstract Co-Author*) Nothing to Disclose

celotus@foxmail.com

PURPOSE

To investigate Haralick texture analysis of pancreatic head mass MRI for differentiating pancreatic head cancer(PHC) from mass-forming chronic pancreatitis at the pancreatic head.

METHOD AND MATERIALS

58 PHC patients, 23 mass-forming chronic pancreatitis patients prior to pancreatoduodenectomy or biopsy and 30 healthy controls undergoing MRI were included. Whole-lesion volumes of interests were placed on T2WI, pre- and post-contrast T1WI, which based on pathological information. Histogram-based parameters and textural features extracted from VOIs were analyzed using generalized estimating equations. The resulting data were processed with Kruskal-Wallis test and binary logistic regression models. Diagnostic accuracy was assessed by area under the receiver operating characteristic curves.

RESULTS

For pre-contrast T1WI, significant differences were observed for 26 matrixes. At binary logistic regression, among the 17 matrixes (AUCs>0.8), significant independent predictors of PHC were Quantile95, Compactness1 with a combined AUC of 0.953 (P=0.000). Combining these two matrixes achieved sensitivity of 89.7% and specificity of 89.7%. On post-contrast T1WI, significant differences were observed for thirty-nine matrixes. At binary logistic regression, among the 18 matrixes (AUCs>0.8), significant independent predictors of PHC were RelativeDeviation, Uniformity, and Compactness1, with a combined AUC of 0.948 (P<0.0001). Combining these three matrixes achieved sensitivity of 86.2% and specificity of 84.9%. PHC has the highest degree of compactness, followed by chronic pancreatitis, and the lowest normal pancreas. PHC shows higher Relative Deviation and lower uniformity than chronic pancreatitis and normal pancreatic tissue. However, chronic pancreatitis and normal pancreas did not differ between these two matrixes. For T2WI significant differences were observed for Skewness, Haralick Correlation, and Inverse Difference Moment, but the AUCs of these parameters were not greater than 0.8.

CONCLUSION

Texture metrics obtained on various MRI sequences, post- contrast T1WI provided the highest, and T2WI the lowest performance for differentiating pancreatic head mass. Several Haralick-based texture features appear useful for distinguishing chronic inflammatory mass from PHC.

CLINICAL RELEVANCE/APPLICATION

Several Haralick-based texture features appear useful for distinguishing chronic inflammatory mass at the pancreatic head and PHC.

PURPOSE

To compare F-18-Fluorodeoxyglucose (FDG)-positron-emission-tomography/magnetic-resonance-imaging (PET/MRI) and PET/computed-tomography (PET/CT) in staging of gastro-esophageal junction (GEJ) cancer.

METHOD AND MATERIALS

Following IRB approval and informed consent, 24 patients with histologically proven GEJ cancer were prospectively recruited; 4 patients were excluded for technical reasons (19 male, 1 female; mean 68.3+/-9.1 years). Patients were injected with 326+/-28 MBq FDG intravenously for the clinical PET/CT. Uptake time was 60 minutes. PET/MRI was acquired directly after the PET/CT. 2 experienced radiologists and nuclear physicians reviewed the images and defined the PET/MRI-TNM stage in consensus. PET/CT NM-stage was defined for clinical routine. Standard of reference was the multidisciplinary team meeting (MDT) stage, which was defined by contrast enhanced CT+/-endoscopic ultrasonography (EUS) and PET/CT. Sensitivity (SE), Specificity (SP), positive predictive value (PPV), negative predictive value (NPV) and accuracy (AC) were calculated. McNemar test was performed to assess differences between different modalities.

RESULTS

For PET/MRI T-stage was concordant with MDT stage in 14 (70%) of 20 patients. Differences in T-stages between PET/MRI and MDT were statistically significant (p=0.03) (Table 1). In our cohort, PET/MRI upstaged three T3 primary lesions as T4 and correctly assigned two T4 lesions. Both PET/MRI and PET/CT agreed in N-and M-staging in all patients. Differences in N-stage between hybrid modalities and MDT were significant (p=0.03) (6 of 20 patients) (Table 2). SE, SP, PPV, NPV and AC for detection of lymph node metastases were 94%, 100%, 100%, 67% and 95% for both imaging modalities.

CONCLUSION

PET/MRI and PET/CT performed similarly in N and M staging. PET/MRI has advantages over PET/CT in providing additional T-stage.

CLINICAL RELEVANCE/APPLICATION

PET/MRI might be used for staging of patients with GEJ cancer in the future.

SSE10-02 Arterial Enhancement Patterns on MR imaging as Preoperative Prognostic Markers of Intrahepatic Mass-forming Cholangiocarcinoma

PURPOSE

This study aimed to evaluate the prognostic factors of intrahepatic mass-forming cholangiocarcinoma (IMCC) and to determine the relationship between the magnetic resonance imaging (MRI) features of IMCC including arterial enhancement pattern, the clinicopathologic factors, and the clinical outcomes.

METHOD AND MATERIALS

The institutional review board approved this retrospective study. The need for informed patient consent was waived. This stud included 134 patients who underwent curative hepatic resection and preoperative MRI for IMCCs (median size: 4.5 cm). The MRIs were reviewed for the IMCCs, which were classified according to the arterial enhancement pattern (diffuse hypoenhancement vs. peripheral rim enhancement vs. diffuse hyperenhancement). We performed survival analysis according to preoperative and postoperative clinicopathologic factors as well as imaging findings.

RESULTS

In multivariate analysis, the CA 19-9 level ($P = 0.010$), tumor size ($P = 0.001$), tumor number ($P = 0.008$), tumor differentiation ($P = 0.036$), vascular invasion ($P < 0.001$), and arterial enhancement pattern ($P < 0.001$) were significant prognostic factors for overall survival (OS). The CA 19-9 level ($P = 0.013$), tumor size ($P = 0.018$), T classification ($P = 0.013$), necrosis ($P = 0.019$), and arterial enhancement pattern ($P = 0.005$) were significant prognostic factors for recurrence-free survival (RFS). There were significant differences in clinicopathologic features among the three arterial enhancement groups. The OS and RFS of the diffuse hyperenhancement group were significantly better than those of the peripheral rim or diffuse hypoenhancement group ($P < 0.001$).

CONCLUSION

The arterial enhancement pattern on MRI, along with the CA 19-9 level and tumor size may be a useful prognostic marker in the preoperative evaluation of patients with IMCC.

CLINICAL RELEVANCE/APPLICATION

The arterial enhancement patterns on MRI are the potential prognostic marker in the preoperative evaluation of patients with IMCC. Patients with IMCC with diffuse hyperenhancement had significantly better clinical outcomes than those with peripheral rim enhancement or diffuse hypoenhancement.

SSE10-03 Clinical Value of Single-Source, Dual-Energy Spectral CT Imaging in Differentiating Small Liver Cyst from Micro-Metastatic Lesion

PURPOSE

To evaluate the value of single-source, dual-energy CT in the differential diagnosis of small liver cysts from micro-metastatic lesions.

METHOD AND MATERIALS

From January 2014 to Oct 2016, 30 patients with 55 liver lesions underwent spectral CT scans. The lesions were divided into two groups: group A (micro-metastatic) and group B (small liver cysts) (all lesions were diagnosed by medical history and follow-up). The mean CT value of the 40-140keV monochromatic images, iodine (water) concentration and effective atomic number (eff-Z) for the lesions were measured on an AW 4.5 workstation The slope of the spectral curve (K) was measured in the two groups and were statistically compared. Receiver operating characteristic (ROC) curves were constructed to evaluate the effectiveness of each parameter.

RESULTS

The consistency of measurements between the observers was rated very well (ICC>0.75). In the unenhanced CT phase, there was no difference in all measurements between the 2 lesion groups ($P>0.05$). The CT values of the 40-70keV images in group A were significantly higher than those in group B in all three contrast-enhanced phases ($P<0.05$). Using the CT value of 79.06HU as a threshold for the 40keV images, one obtained an area-under-curve (AUC) for ROC study of 0.802 with sensitivity of 87.5% and specificity of 61.3% for differentiating small liver cysts from micro-metastatic lesions. The iodine concentration, eff-Z and K measurements were different between the two lesion groups only in the arterial phase ($P<0.05$) (AUC=0.747, 0.765, 0.753). Through combining the CT value at 40keV, iodine concentration, eff-Z and K values in the arterial phase, we could obtain an pooled sensitivity of 90.3%, specificity of 66.7% with a pooled AUC of0.856.

CONCLUSION

Single-source dual-energy CT provides multiple parameters for relatively high diagnostic accuracy in differentiating small liver cysts from micro-metastatic lesions.

CLINICAL RELEVANCE/APPLICATION

Single-source dual-energy CT has good clinical value in differentiating small liver cyst from micro-metastatic lesion.

SSE10-04 Volumetric Measurement of Split and Merged Target Lymph Nodes on CT in Clinical Trials, Compared with RECIST Version 1.1

PURPOSE

To investigate the volumetric changes of split or merged target lymph node on CT scans compared with Response Evaluation Criteria in Solid Tumors (RECIST) version 1.1 measurements.

METHOD AND MATERIALS

Target lymph nodes (short axis diameter >= 1.5 cm) that separated from a conglomerate node (split node) or merged with other nodes (merged node) were retrospectively examined at multiple time points in a cohort of 182 patients with cancers enrolled in clinical trials. Each target node was measured in PACS (Carestream Health) based on RECIST 1.1 before and after splitting or merging, and percent size change was calculated. Volumetric changes of the nodes were also calculated using Vitrea Enterprise Suite V:6.8.0, with percent change recorded as the ground truth. RECIST and volumetric measurements were compared using a t-test. Our cohort was categorized into 3 groups: a conglomerate node splits, one target node merge with other nodes (one-target merged), and two neighboring target nodes merge (two-target merged) as RECIST allows a maximum of two target lymph nodes per patient.

RESULTS

Our cohort consisted of 20 split nodes and 30 merged nodes (19 were 1-target merged, and 11 were 2-target merged). A significant difference ($p<0.001$) was seen in all groups between RECIST and volumetric measurements. Mean percent change in size of split nodes was +1% range -48% to +52%) by RECIST and -66% (range from -98% to -13%) by volumetric method. Mean percent change in size of one-target merged nodes was 65% (range 29% to 107%) by RECIST and 210% (range 15% to 607%) by volumetric method. Mean percent change in size of two-target merged nodes was -15% (ranging from -31% to -4%) by RECIST and 110% (ranging from 15% to 234%) two-target merged. While volumetric measurements indicated a decrease in size of all split nodes, RECIST measurements indicated an increase in size in 60% of cases. In merged nodes, volumetric measurements indicated an increase in size for both merged groups, while RECIST measurement showed a decrease in size in all 2-target merged nodes (11 of 11).

CONCLUSION

RECIST 1.1 may not accurately represent the volumetric increase or decrease in size of target lymph nodes during merging or splitting events.

CLINICAL RELEVANCE/APPLICATION

Volumetric analysis of split and merged lymph nodes indicates a need for revision of target lymph node measurement methodologies of RECIST version 1.1.

SSE10-05 Is There a Direct Correlation Between Microvascular Wall Structure and K-Trans Values Obtained from Perfusion-CT Measurements in Lymphomas?

Monday, Nov. 26 3:40PM - 3:50PM Room: S403A

PURPOSE

To test the hypothesis that ultrastructural wall abnormalities of lymphoma vessels correlate with CT perfusion kinetics.

METHOD AND MATERIALS

Our local institutional review board approved this prospective study. Between February 2013 and June 2016, we included 23 consecutive subjects with newly diagnosed lymphoma, who were referred for CT-guided biopsy (6 female, 17 male; mean age, 60.61±12.43years; range, 28-74 years) and additionally agreed to undergo perfusion-CT of the target lymphoma tissues. Perfusion-CT was obtained for 40 seconds using 80 kV, 120 mAs, 64 x 0.6 mm collimation, 6.9 cm z-axis coverage, and 26 volume measurements. Mean and maximum k-trans (ml/100ml/min), blood flow (BF; ml/100ml/min) and blood volume (BV) were quantified using the deconvolution and the maximum slope + Patlak calculation models. Immunohistiochemical staining was performed for microvessel density (MVD) quantification (vessels/m2) and electron microscopy was used to determine the presence or absence of tight junctions, endothelial fenestration, basement membrane, pericytes and for measurement of extracellular matrix thickness

RESULTS

Extracellular matrix thickness as well as the presence/absence of tight junctions, basal lamina and pericytes did not correlate with CT perfusion parameters. Endothelial fenestrations correlated significantly with mean BFdeconvolution ($p=0.047, r=0.418$), and additionally was significantly associated with higher mean BVdeconvolution ($p<0.005$). Mean k-transPatlak correlated strong with mean k-transdeconvolution ($r=0.939, p=0.001$), and both correlated with mean BFdeconvolution ($p=0.001, r=0.748$), max BFdeconvolution ($p=0.028, r=0.564$), mean BVdeconvolution ($p=0.001, r=0.752$) and max BVdeconvolution ($p=0.001, r=0.771$). MDV correlated with max k-transdeconvolution($r=0.564, p=0.023$).

CONCLUSION

K-trans values of perfusion CT do not correlate with ultrastructural microvessel features, whereas endothelial fenestrations correlate with increase intra-tumoral blood volumes.

CLINICAL RELEVANCE/APPLICATION

Numerous imaging studies have been conducted with the aim of non-invasively quantify tumor vascularization and vessel wall leakiness. However, to the best of our knowledge, an association between electron microscopy-based ultrastructural vessel wall features and PCT kinetics of lymphoma has not been investigated. Therefore, we tested the hypothesis that ultrastructural wall abnormalities of lymphoma vessels correlate with PCT kinetics.

SSE10-06 Nationwide, Longitudinal Trends in CT Colonography Usage: Cross Sectional Survey Results from the 2010 and 2015 National Health Interview Survey

Monday, Nov. 26 3:50PM - 4:00PM Room: S403A

aknarayan@mgh.harvard.edu

PURPOSE

Colorectal cancer screening reduces mortality however screening rates have plateaued. Prior studies have found that giving patients choices between different screening tests improves adherence. CT colonography is an emerging minimally invasive screening test that demonstrates high sensitivity for colonic polyps(>1 cm). With increasing health insurance coverage, there are limited national, population-based estimates of CT colonography utilization over time. Our purpose was to estimate longitudinal utilization of CT colonography among eligible participants using nationally representative cross sectional survey data.

METHOD AND MATERIALS

We used nationally representative cross sectional survey data from 2010 and 2015 National Health Interview Surveys including information about CT colonography usage. 2010 response rate was 77% and 2015 response rate was 80%. Participants between ages 50-75 without histories of colon cancer were included. Logistic regression analyses were used to evaluate longitudinal changes in the proportion of eligible individuals undergoing CT colonography, adjusted for potential confounders and stratified by type of health insurance and age category. Analyses were conducted taking into account complex survey design elements (adjusted weights, strata and sampling units).

RESULTS

8,965 survey respondents in 2010 and 12,721 survey respondents in 2015 were included. 1.2% reported usage of CT colonography in 2010 and 0.9% reported usage of CT colonography in 2015, a statistically significant decrease (Adjusted OR 0.92, 95% CI 0.86 - 0.99). Optical colonoscopy usage increased from 57.9 to 63.6% (Adjusted OR 1.04, 95% CI 1.02 - 1.06). In our stratified analyses, patients with private health insurance($p = 0.35$), patients below 65 (not Medicare eligible)($p = 0.07$) and patients who had heard of CT colonography($p = 0.28$), did not experience changes in CT colonography usage. Overall awareness of CT colonography decreased from 20.5% to 15.9%, a statistically significant decrease (Adjusted OR 0.94, 95% CI 0.92 - 0.96).

CONCLUSION

Despite increasing overall usage of optical colonoscopy from 2010 to 2015, CT colonography awareness(~16%) and utilization(~1%) remained low.

CLINICAL RELEVANCE/APPLICATION

Improved public awareness and coverage expansion to Medicare age populations will promote increased CT colonography utilization and improvements in overall colorectal cancer screening.

SSE11-01 Three Dimensional Texture Analysis with Machine Learning Provides Incremental Predictive Information for Successful Shock Wave Lithotripsy in Patients with Kidney Stones

Monday, Nov. 26 3:00PM - 3:10PM Room: S102CD

Participants
Manoj Mannil, Zurich, Switzerland (*Presenter*) Nothing to Disclose
Jochen von Spiczak, MD,MSc, Zurich, Switzerland (*Abstract Co-Author*) Nothing to Disclose
Christian Fankhauser, Zurich, Switzerland (*Abstract Co-Author*) Nothing to Disclose
Thomas Hermanns, Zurich, Switzerland (*Abstract Co-Author*) Nothing to Disclose
Hatem Alkadhi, MD, Zurich, Switzerland (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To determine the predictive value of three-dimensional texture analysis (3D-TA) in computed tomography (CT) images for successful shock wave lithotripsy (SWL) in patients with kidney stones.

METHOD AND MATERIALS

Patients with pre and postoperative CT scans, previously untreated kidney stones and a stone diameter of 5-20 mm were included. A total of 224 3D-TA features of each kidney stone, including the attenuation measured in Hounsfield Units (HU), and the clinical variables body mass index (BMI), initial stone size, and skin-to-stone distance (SSD) were analyzed using five commonly used machine learning models. The data set was split in a ratio of 2/3 for model derivation and 1/3 for validation. Machine learning-based predictions for SWL success in the validation cohort were evaluated calculating sensitivity, specificity, and the area-under-the-curve (AUC).

RESULTS

For SWL success the three clinical variables BMI, initial stone size and SSD showed AUCs of 0.68, 0.58 and 0.63 respectively and no predictive information for HU could be noted. By use of a RandomForest classifier using three 3D-TA features an AUC of 0.79 could be observed. By combining 3D-TA features and clinical variables, the discriminatory accuracy improved further with an AUC of 0.85 for 3D-TA features and SSD, an AUC of 0.8 for 3D-TA features and BMI and an AUC of 0.81 for 3D-TA and stone size.

CONCLUSION

Our in-vivo study indicates the potential of 3DTA of urinary stone CT enabling the prediction of successful stone disintegration with SWL with high accuracy.

CLINICAL RELEVANCE/APPLICATION

Selected 3D-TA features provide incremental predictive value for successful SWL, which allows stratifying patients with symptomatic kidney stones to either primary SWL or Ureterorenoscopy.

SSE11-02 Usefulness of Computer Aided Detection of Urinary Stones in Computed Tomography Kidney Ureter Bladder using Convolutional Neural Networks: Preliminary Study

pksungbin@paran.com

PURPOSE

Computed tomography kidney ureter bladder (CTKUB) is the method of choice for diagnosing urinary stones. The purpose of this study is to develop a computer aided detection (CAD) algorithm for identifying a urinary stone in thin slice CTKUB.

METHOD AND MATERIALS

Thin slices (3 mm) CTKUB (120 kVp and 150 mAs) in patients with suspicious of stone disease were included in the study. The labeling of urinary stones or not in CTKUB as reference standard was performed by an expert radiologist. 5,268 urinary stones and 4,980 non-urinary stones on CTKUB images were evaluated for training dataset. 551 urinary stones and 528 non-urinary stones on CTKUB images were evaluated for validation dataset. The convolutional neural network was consisted of 8 convolution layers, 9 fully connected layers and softmax classifier. The diagnostic performance of CAD algorithm for identifying a urinary stone from combination of three different image planes (axial, coronal and sagittal) in thin slice CTKUB using convolutional neural network was analyzed.

RESULTS

In training dataset, the performance was almost perfect. In validation dataset, the CAD algorithm was classified all 551 urinary stones as stones. It was also classified 528 non-urinary stones as 527 non-urinary stones and 1 urinary stone. The sensitivity, specificity, accuracy, positive predictive value and negative predictive value of CAD algorithm were 100%, 99.8%, 99.9%, 99.8% and 100%, respectively.

CONCLUSION

CAD algorithm in thin slice CTKUB using convolutional neural network can have high diagnostic performance for urinary stone detection. Prospective further studies involving more participants and focusing on the factors affecting clinical practice such as stone size, location (ureter, kidney) are needed.

CLINICAL RELEVANCE/APPLICATION

In view of its high accuracy, we believe CAD algorithm in thin slice CTKUB using convolutional neural network can be used as an initial examination in patients with suspicious of stone disease.

SSE11-03 Efficacy of Single-Source Rapid kV-Switching Dual-Energy CT for Characterization of Non-Uric Acid Renal Stones: A Prospective Ex-Vivo Study Using Anthropomorphic Phantom

PURPOSE

To investigate the accuracy of rapid kV-switching single-source dual-energy computer tomography for prediction of classes of non-uric acid stones.

METHOD AND MATERIALS

Non-uric-acid renal stones retrieved via percutaneous nephrolithotomy were prospectively collected between January 2017 and February 2018 in a single institution. Only stones >5mm and with pure composition (i.e. >80% composed of one element) were studied. Stone composition was determined using Fourier Transform Infrared Spectroscopy. The stones were scanned in 32 cm-wide anthropomorphic whole body phantom in a location mimicking the kidneys. Image acquisition was performed using a single-source rapid-kVp switching CT scanner. The effective atomic number (Zeff) and the attenuation (HU) at 40 kev, 70 kev, and 140 kev virtual monochromatic sets of images were extracted by placing a ROI at the largest cross-sectional areas. Ratios between the attenuations at different energy levels were calculated. Mean values of different stone classes were compared using ANOVA and student t-test. Difference between the actual class of stone and the predicted class of stone based on vendor-recommended Zeff thresholds were assessed. A p-value <0.05 was considered statistically significant. Receiver operating curves (ROC) and area under curve (AUC) with 95% confidence intervals were calculated to assess the efficacy of each parameter.

RESULTS

The final study sample included 31 stones from 31 patients consisting of 2 (6%) struvite, 4 (13%) cysteine and 25 (81%) calcium-based pure stones. The mean size of the stones was 9.9 ± 2.4 mm. The mean Zeff of the stones was 12.0±0.41 for calcium-based, 10.1 ± 0.14 for struvite, and 9.9 ± 0.57 for cysteine stones which were statistically different ($p<0.001$). In 16 cases (51.6%), there was discrepancy between the actual stone class and the predicted class based on vendor-recommended thresholds. Zeff had the best efficacy for differentiation of different stone classes. The calculated AUC was for 0.947 for Zeff; 0.833 for HU40; 0.880 for HU70 and 0.893 for HU140.

CONCLUSION

Zeff has superior performance to HU and attenuation ratios for differentiation of different classes of non-uric-acid stones.

CLINICAL RELEVANCE/APPLICATION

Non-invasive determination of composition of urinary stone has important clinical implication in guiding the decision making algorithm

for stone treatment.

SSE11-04 Dual-Energy Spectral CT Characterization of Urinary Calculi In Vivo

Monday, Nov. 26 3:30PM - 3:40PM Room: S102CD

Participants
Xiaohu Li, MD, Hefei, China (*Presenter*) Nothing to Disclose
Yongqiang Yu, MD, Hefei, China (*Abstract Co-Author*) Nothing to Disclose
Jianying Li, Beijing, China (*Abstract Co-Author*) Employee, General Electric Company

PURPOSE

To explore the feasibility of using dual-energy energy spectral CT to determine the components of urinary calculi in vivo

METHOD AND MATERIALS

Fifty-seven cases of patients with urinary calculi were included in the present eighty-nine stones,with GSI (gemstone spectral imaging) scan using AW4.6 workstation for image analysis indexes:GSI scan mode (Effective atomic number), the material (Materia Density) calcium water ratio (calcium water ratio, CWR),50keV and 70keV single energy CT value. The differences of 4 indexes were compared. According the infrared spectrum analysis results as the reference standard. Compared with spectrum diagnosis ,we can conclude that sensitivity, specificity and positive predictive value, negative predictive value of pure uric acid stones, pure non-uric acid stones, stones mixed . Retrospective study of involving 24 cases of single component calculi (11 pieces of uric acid stones, 9 pieces of calcium oxalate, 3 pieces of calcium phosphate stones) and 53 cases of mixed stones.Stones were respectively measuring the effective atomic number, CWR, 50ke V, 70keV single energy CT value and we can compare the indexes of different groups with the one way anova.

RESULTS

The infrared spectrum analysis results as the reference standard, the sensitivity for analysis pure uric acid calculi, pure non-uric acid stones and mixed stones were 100%, 91.7%, 97.0% ,respectively;with specificity of 100%, 97.4%, 95.7% ,respectively;with the positive predictive value of 100%, 84.6% 98.5% respectively and the negative predictive value were 100%, 98.7%, 91.7% ,respectively.

CLINICAL RELEVANCE/APPLICATION

It is useful to reduce the occurrence of complications if we can make a definite diagnosis of stone composition before surgery.

SSE11-05 Role of Single Source Dual Energy CT in Evaluation of Chemical Composition of Urinary Tract Calculi

PURPOSE

To evaluate the diagnostic accuracy of Single Source Dual Energy CT in characterisation of renal stones with biochemical analysis as reference

METHOD AND MATERIALS

This was a prospective study carried out at a tertiary care centre for a period of 3 years using Gemstone Spectral Imaging in single source dual energy CT scanner- GE Discovery CT750 HD. A total of 70 patients with renal calculi who underwent single source dual energy CT and subsequent surgery were included in the study. Both high and low energy data sets are acquired simultaneously for axial and helical acquisitions at the full 50 cm field of view. Dual-energy data were processed by the GSI general protocol on the CT workstation (Advantage Windows, version 4.2; GE Healthcare). A region of interest (ROI) was applied over the renal stone viewed on the bone window settings occupying approximately 50% of the stone area on axial images. Using GSI software effective atomic number of the ROI area Z (Zeff) was calculated and stones were characterised. Post surgery biochemical analyses of these stones were sent to a common laboratory. All results of dual energy CT were compared to the biochemical analysis by applying kappa statistics

RESULTS

Out of 70 patients, 43 were male and rest were female. The age group of patients ranged from 25 to 70 years (mean 47 years). Out of 48 calcium oxalate stones on dual energy CT, 47 were calcium oxalate and one was mixed. Out of 12 struvite stones on dual energy CT, 10 were struvite and 2 were mixed. Single cysteine stone detected on dual energy CT was found to be mixed stone on biochemistry. All 7 ammonium urate stones on dual energy were found to be same on biochemistry. Single mixed stone detected on dual energy CT showed similar result on biochemistry. Weighted kappa was found to be 0.835 which indicates very good agreement between two different diagnostic tests

CONCLUSION

Single Source Dual energy CT scan has a role in accurately assessing the chemical composition of the urinary tract calculi

CLINICAL RELEVANCE/APPLICATION

Chemical composition of the urinary tract calculi using Single Source Dual Energy CT has significant impact on medical management of patient with stone disease

SSE11-06 Comparison of CT-Index and Effective Z Analysis for Characterization of Urinary Stones with Dual-Energy CT: A Phantom Study

Monday, Nov. 26 3:50PM - 4:00PM Room: S102CD

felice.burn@ksa.ch

PURPOSE

To assess the accuracy of CT-index and effective Z value (atomic number) derived from dual-energy CT for differentiation of uric acid from non-uric acid stones and to further characterize the subgroup of non-uric acid stones.

METHOD AND MATERIALS

Total of 64 urinary stones from humans (32 uric acid and 32 non-uric acid stones with subgroups of oxalate, struvite, brushite and apatite) were included in the study. The stones were placed in an anthropomorphic CT-phantom (diameter, 30 cm). All stones underwent an x-ray diffraction analysis representing the gold standard and they had a high purity and homogeneity of at least 90% in their compositions. The phantom was scanned on a 360-slice MDCT scanner (Aquilion ONE Vision, Canon Medical) with a dual-energy mode using tube voltages of 135 and 80 kVp. The acquired datasets were automatically segmented and postprocessed with commercially available software. The CT-index and the effective Z, which was derived from raw data-based dual-energy analysis, was assessed. A statistical receiver operating characteristics (ROC) analysis and multivarable discrimination analysis was performed.

RESULTS

The differentiation of uric acid stones from non-uric acid stones were significant, using the CT-index ($p < 0.001$) and the effective Z value ($p < 0.01$). The use of the effective Z and CT-index allow further separation in subcategories as uric acid, oxalat, apatit, brushit and struvit stones (Figure 1), whereas this separation is less accurate than for the differentiation of uric acid from non-uric acid stones. If the CT-index and the effective Z values were taken both in consideration a subgroup analysis shows. If the CT-index and the effective Z values were taken both in consideration a subgroup analysis shows more powerful options in differentiation.

CONCLUSION

CT-index and effective Z values, derived from dual-energy CT, allow very accurate differentiation of uric acid from non-uric acid stones. The differentiation of non-uric acid subgroups is not very reliable for both parameters separately. However, the combinations of both parameters in the evaluation of subgroups can improve the separation of non-uric acid stones.

CLINICAL RELEVANCE/APPLICATION

Improved characterization of renal stone compositions with dual-energy CT using CT index and effective Z value in combination has a direct impact on the clinical management and therefor may improve patient outcome and may reduce treatment costs.

Guido M. Kukuk, MD, Bonn, Germany (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic value of six-echo modified Dixon (mDixon) fat quantification techniques in the differentiation between benign and malignant adrenal masses.

METHOD AND MATERIALS

All dedicated upper abdominal MRI examinations including proton density fat fraction (PDFF) maps of the year 2015 (n=535) were re-evaluated for the presence of adrenal incidentalomas. PDFF values acquired by placing one single ROI were compared to adrenal signal intensity index (ASII, [(signal intensity on in-phase imaging - signal intensity on opposed-phase imaging) / (signal intensity on in-phase imaging)] × 100%) and adrenal-to-spleen chemical-shift ratio (ASR, ([(signal intensity of lesion on opposed-phase imaging - signal intensity of spleen on opposed-phase imaging) / (signal intensity of lesion on in-phase imaging - signal intensity of spleen on opposed-phase imaging)]-1) × 100%) for all lesions by two independent readers. All lesions were interpreted in the clinical context including -if available- histological results, interdisciplinary tumor board decisions and follow-up examinations.

RESULTS

Fifty-five patients with 70 lesions were identified. 47 lesions (67.1%) were finally diagnosed as adenomas, 23 lesions (32.9%) were confirmed adrenal metastases. Applying PDFF maps a fat fraction of at least 8.3% was 100% sensitive and 91.7% specific for the diagnosis of adrenal adenoma (AUC: 0.996). A fat fraction of at least 12.25% showed a sensitivity of 91.5% and specificity of 100% in detecting adenomas ruling out all possible malignant adrenal masses. PDFF measurements were significantly more observer independent than calculations of ASII and ASR ($p < 0.05$).

CONCLUSION

Six-echo mDixon fat quantification technique provides a robust, fast and highly observer independent tool for the distinction between benign and malignant adrenal masses.

CLINICAL RELEVANCE/APPLICATION

Providing a high diagnostic accuracy and superior inter-rater variability compared to ASII and ASR PDFF maps might replace the established indices in the evaluation of adrenal masses.

SSE12-03 Adrenal Nodules Greater Than 10 Hounsfield Units (HU) on Non-Contrast CT: Still Indeterminate?

PURPOSE

To determine if a Gaussian-based algorithm (GA) analysis with and without noise correction can help characterize indeterminate adrenal nodules (> 10HU) on non-contrast CT as lipid poor adenomas.

METHOD AND MATERIALS

IRB-approved, HIPAA-compliant retrospective study evaluated adrenal nodules greater than 1 cm on non-contrast CT using the GA based region of interest histogram analysis with and without noise correction (normalization of mAs, kVp, and slice thickness to published data). Two independent readers evaluated the nodules and were blinded to final pathology. Lesions were characterized as malignant if pathology proven by biopsy or surgical resection or likely benign due to pathology or imaging features (stability > 1 year, adrenal CT washout, MRI signal loss, or negative FDG PET/CT with a FDG positive primary). Inter-reader agreement was assessed using intraclass correlation coefficient (ICC). Sensitivity, specificity and area under the curve (AUC) were derived.

RESULTS

There were 91 adrenal nodules in 83 patients that averaged 2.6 cm in size (±1.9 cm). 33 nodules were pathologically confirmed metastases most commonly lung cancer: average size 1.7 ± 0.7 cm, mean attenuation 23.8 ± 8.8 HU. 58 nodules were presumed to be adenomas based on imaging characteristics: average size 3.9 ± 2.6 cm, mean attenuation 32.2 ± 8.2 HU. Inter-reader agreement was excellent (ICC > 0.8) for multiple variables, including nodule size, mean attenuation, SD of attenuation, and G-index. The noise-corrected GA had significantly higher specificity (85% vs. 59%, p<0.001) and lower sensitivity (38% vs. 58%, p<0.001) for identifying adenoma than the uncorrected GA. The AUC for the corrected GA-index was 0.74, which was statistically improved compared to uncorrected GA-index (0.52, p=0.04) while being similar to the mean attenuation (0.78, p=0.1) and size (0.81, p=0.3).

CONCLUSION

A Gaussian-based algorithm based on histogram analysis can discriminate between lipid-poor adrenal adenomas and non-adenomas, although it performed no better than an alternative mean attenuation cutoff.

CLINICAL RELEVANCE/APPLICATION

Noise correction Gaussian based algorithm can be used to assess indeterminate adrenal nodules >10HU with high specificity, however further workup may still be needed in patients with a history of cancer.

SSE12-04 Correlation Between Subclinical Hypercortisolism and Adrenal Volumetry in Patients with Incidental Adrenal Adenoma

Monday, Nov. 26 3:30PM - 3:40PM Room: S103AB

Participants
Nicolas Mertens Folch, Santiago, Chile (*Presenter*) Nothing to Disclose
Roberto I. Olmos, MD, Santiago, Chile (*Abstract Co-Author*) Nothing to Disclose
Rene Baudrand, Santiago, Chile (*Abstract Co-Author*) Nothing to Disclose
Alvaro Huete Garin, MD , Santiago, Chile (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To correlate lesion and contralateral adrenal gland volume (CLAV) measurements in asymptomatic patients with incidental adrenal adenoma (IAA) found on computed tomography (CT) with the presence of subclinical hypercortisolism (SCH).

METHOD AND MATERIALS

50 consecutive subjects with IAA were prospectively enrolled after obtaining informed consent between August 2016 and January 2018 according to local scientific ethics committee guidelines. Dexamethasone suppression test and ACTH quantification in peripheral blood was performed in all patients to diagnose SCH. All subjects underwent an adrenal protocol CT with iodinated intravenous contrast and lesion was confirmed as adenoma using known diagnostic criteria (non contrast density < 10 HU, relative washout > 40%, absolute washout > 60%). Volume of the IAA and the CLAV was calculated with Osirix® viewer software by 2 reviewers, with reproducibility evaluated using Bland-Altman analysis. Mann-Whitney U test was used for statistical correlation. Receiver operating characteristic (ROC) curves were obtained to determine the discrimination capabilities of each variable.

RESULTS

Subjects included had a mean age of 57.2 years, 82% (n=41) were female. 12 subjects (24%) from the group were diagnosed with SCH. Patients with SCH had larger IAA volumes (p<0.0001) and lower CLAV (p=0.005) than those without SCH. The Bland-Altman analysis showed acceptable inter-reader measurement agreement and moderate dispersion of the results, especially at higher IAA and CLAV volumes, with a mean difference of 0.09 cm3, 95% CI [-1.4, 1.58] for IAA volume and a mean difference of 0.42 cm3, 95% CI [-2.69, 3.53] for CLAV. Area under the ROC curve (AUC) for IAA volume and CLAV was 0.936, 95% CI [0.869, 1] and 0.822, 95% CI [0.668, 0.976] respectively.

CONCLUSION

IAA volume and CLAV appear to be useful and reproducible tools predicting the presence of SCH in asymptomatic patients with IAA.

CLINICAL RELEVANCE/APPLICATION

Endocrinologic work-up may be advised for patients with IAA and volumetric markers suggesting SCH.

SSE12-05 Hollowed Adrenal Gland Sign in Patients of Septic Shock: Incidence, CT Appearance and Prognosis

Monday, Nov. 26 3:40PM - 3:50PM Room: S103AB

Participants
Yang Peng, Guangzhou, China (*Presenter*) Nothing to Disclose
Qiuxia Xie, Guangzhou, China (*Abstract Co-Author*) Nothing to Disclose

usefulkey0077@hotmail.com

PURPOSE

To investigate the incidence, CT appearance and prognosis of hollowed adrenal gland sign in septic shock patients.

METHOD AND MATERIALS

From January 2014 to May 2017, there were181 patients with septic shock in ICU (mean 60.7 years; range 19-89 years; 112 males, 69 females). All the patients received dual-phase enhanced CT scan in one week after diagnosis. CT findings and clinical records were reviewed retrospectively. When patients showed diffuse enlargement of bilateral adrenal glands on CT, and in arterial phase the central area of adrenal gland showed much lower attenuation while in venous phase the central "hollowed" area showed further enhancement and was similar to the peripheral area, they were defined as hollowed adrenal gland sign positive. Single factor analysis was performed.

RESULTS

59 patients showed hollowed adrenal gland sign (32.6%, 59/181) as positive group, while the remain 122 patients were negative. Total mortality rates of positive group and negative group were 81.3% (48/59) and 49.1% (60/122), respectively. According to the primary diseases causing septic shock, patients in both groups were divided into 4 subgroups (intestinal diseases, biliary and pancreatic diseases, postoperative infection and others). The mortality rates of 4 subgroups in positive group were 75.0% (12/16), 66.7% (10/15), 91.7% (22/24), and 100% (4/4), respectively. And the mortality rates of 4 subgroups in negative group were 43.8% (14/32), 28.6% (8/28), 64.3% (27/42) and 55.0% (11/20), respectively. There were significant difference of total mortality rates and mortality rates of matching subgroups between two groups ($P<0.01$). Single factor analysis of variance showed that the hollowed adrenal gland sign was an independent factor to predict a poor prognosis (death) for septic shock patients.

CONCLUSION

Hollowed adrenal gland sign is common on CT in septic shock patients and predicts a poor prognosis.

CLINICAL RELEVANCE/APPLICATION

Hollowed adrenal gland sign is a typical CT appearance of septic shock patient with relative adrenal insufficiency, and appears to be an independent adverse prognostic factor.

SSE12-06 Adrenal Incidentalomas: A New Risk Factor for Overall Mortality?

Monday, Nov. 26 3:50PM - 4:00PM Room: S103AB

PURPOSE

To determine the mortality risk of adrenal incidentaloma on abdominal CT.

METHOD AND MATERIALS

Retrospective cohort study at a multicenter academic medical center. Cohort was identified from patients with newly detected adrenal incidentaloma on CT abdomen report; the primary outcome was all-cause mortality. Study population was derived from patients >=18 years with CT abdomen within 24 hours of emergency department presentation 1/1/05-12/31/09 without history of adrenal disease, adrenal lab testing, or cancer. Incidentaloma cohort was identified by database query of CT reports, followed by manual review to exclude misclassifications. Confirmed incidentaloma cohort was matched to 'no nodule' controls at 3:1 on age ±1 year and exam date ±3 months. Mortality was ascertained by database query for in-hospital deaths and supplemented with National Death Index query for those lost to follow-up. Survival analysis performed with Kaplan-Meier curves and Cox proportional hazards model examining the effect of adrenal incidentaloma on all-cause mortality.

RESULTS

Initial query yielded a population of 42,575 adults with CT abdomen, mean age 50 ±19 years, 63% women. 969 (2.3%) patients had confirmed adrenal incidentalomas and were matched with 2,907 controls. These 3,876 individuals entered survival analysis with 31,182 total person-years follow-up, median follow-up 8.8 years (IQR 6.0-10.6) in the incidentaloma cohort and 9.0 years (IQR 7.1-

10.7) in the no nodule cohort. Mortality was 36.4% (353/969) in the incidentaloma cohort and 31.6% (919/2907) in the no nodule cohort for a rate difference of 7.6 deaths/1000 person-years (95% CI 2.1-13.0; p=0.005). Adrenal incidentaloma presence was associated with an unadjusted 19% increased risk of death (HR 1.19; 95% CI 1.05-1.36) and a 14% increased risk of death when adjusted for age, sex, race, and other significant predictors including diabetes (HR 1.14; 95% CI 1.01-1.29).

CONCLUSION

Incidentally discovered adrenal nodules are associated with a significant though small increased risk of all-cause mortality.

CLINICAL RELEVANCE/APPLICATION

The clinical significance of adrenal incidentalomas remain understudied; results of the present study suggest that incidentalomas may not be as harmless as previously thought.

mhiatt@guardanthealth.com

PURPOSE

In the context of recent concerns about inappropriate utilization of advanced diagnostic imaging (ADI) and the associated deleterious effects of excessive radiation exposure, a radiology benefit manager implemented a program to assist a multi-state health insurance plan manage the use of outpatient ADI, encouraging the withdrawal of inappropriate requests or change to a more appropriate modality (such as ultrasound or MRI in lieu of CT, when indicated). This study investigated the impact of this program.

METHOD AND MATERIALS

A utilization management program was instituted in the middle of 2009 in 2 states in the U.S., and in the middle of 2011 in 2 additional states, to manage the utilization of CT, MRI, PET, and cardiac nuclear medicine (CNM) in accord with appropriateness criteria for the 1.6 million commercial and Medicare members of a health insurance plan. Utilization for each modality was monitored via claims data for 1 year prior to implementation and during the program (through the end of 2015) and expressed in terms of units per 1,000 members (UPK).

RESULTS

Across all 4 states after implementation, utilization declined from 60.1 to 52.0 UPK for CT (-14%), 63.7 to 55.6 for MRI (-13%), 2.2 to 1.9 for PET (-15%), and 7.2 to 3.4 for CNM (-53%) in the commercial population and from 277.2 to 226.8 for CT (-18%), 152.5 to 132.4 for MRI (-13%), and 48.3 to 27.2 for CNM (-44%) in the Medicare population, but increased from 10.9 to 11.5 for PET (+5%) in the Medicare population.

CONCLUSION

After program implementation, utilization declined for all studied modalities in all states for all populations except for PET in the Medicare population.

CLINICAL RELEVANCE/APPLICATION

The imposition of appropriateness criteria in the ordering process through a radiology benefit management program may significantly alter the utilization of ADI for the modalities managed.

SSE13-02 Exploring CMS Quality Measure #405 for Small Incidental Abdominal Lesions

Monday, Nov. 26 3:10PM - 3:20PM Room: S403B

Participants
Bari Dane, MD, New York, NY (*Presenter*) Nothing to Disclose
Andrew B. Rosenkrantz, MD, New York, NY (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

bari.dane@nyumc.org

PURPOSE

One measure that CMS has adopted to evaluate and adjust Medicare payments for radiologists under the Merit-Based Incentive Payment System is measure #405, relating to appropriate follow-up imaging recommendations for incidental abdominal lesions. Measure #405 reflects the fraction of incidental <=0.5 cm liver, <1 cm cystic renal, and <=1 cm adrenal lesions detected on CT,

MRI, or ultrasound, for which radiologists recommend follow-up imaging (lesions excluded in presence of malignancy or other medical reason). A rate of 0% indicates perfect performance. We assessed outcomes of lesions encompassed by CMS quality measure #405.

METHOD AND MATERIALS

1,000 consecutive incidental lesions fulfilling measure #405 criteria were identified. Reports were reviewed for follow-up recommendations. Subsequent imaging, whether or not performed specifically for index lesion follow-up, was assessed for size increase or evidence of lesion malignancy.

RESULTS

The final cohort included 378 ultrasound, 313 CT, and 311 MRI exams, demonstrating 150 liver, 738 renal, and 112 adrenal lesions. Follow-up imaging was recommended in 3% (33) of patients, including 55% (18) of ultrasound exams. Follow-up imaging was obtained in 58% (19) of the 33 recommended cases, compared with at least one subsequent exam in 52% of lesions without a recommendation (p=0.560). Subsequent cross-sectional imaging occurred for a total of 517/1000 cases (>=6 months follow-up in 428 cases; >=1 year in 358). On subsequent imaging, one renal cyst detected on ultrasound showed low-level enhancement on MRI, and three simple renal cysts demonstrated slight size increase; no other lesion in the cohort showed a size increase or evidence of malignancy. No follow-up was recommended for any of these 4 lesions on the baseline exam.

CONCLUSION

Small incidental lesions encompassed by CMS quality measure #405 (most commonly renal cysts on ultrasound) have an extremely minimal risk of being clinically important. Radiologists' recommendations for follow-up did not seem to drive subsequent imaging rates nor detection of the very rare potentially relevant outcome for such lesions. The findings support the measures aim of avoiding follow-up recommendation for these lesions.

CLINICAL RELEVANCE/APPLICATION

The findings support CMS measure #405 that avoids follow-up recommendations for small incidental abdominal lesions. Radiologists should consider using the measure to optimize their MIPS performance.

SSE13-03 Vertebral Fracture Assessment (VFA) Utilization, 2005-2016: A COARDRI Study

Monday, Nov. 26 3:20PM - 3:30PM Room: S403B

For information about this presentation, contact:

robert.ward@tufts.edu

PURPOSE

To characterize utilization of VFA since 2005 with emphasis on the impact of the 2007 DXA reimbursement cut.

METHOD AND MATERIALS

Data was derived from the CMS Medicare Part B Physicians/Supplier Procedure Summary Master Files from 2005 through 2016. Codes 76077, 77082, and 77085 were utilized.

RESULTS

1.713,443 VFA procedures were evaluated from 2005 to 2016. Over that period of time non radiologists billed 74.9% of the studies, 23.0% were billed by radiologists, and 2.1% were unknown. The overall trend in utilization over this period mirrors DXA utilization with decreased utilization (-44.8%) for non-imagers since the 2007 DXA reimbursement cut. Likewise, trending increases in radiologist utilization (+30.6) is noted over the same period. As VFA is performed concurrently with DXA we corrected for DXA trends by utilizing a VFA/DXA ratio. Non-radiologists demonstrated a increasing trend of VFA cases relative to DXA over 2005 to 2016 increasing from 5.8% to 9.2% in 2016. Radiologists in comparison ranged from 1.7% in 2005 to 2.7%. The top 5 specialties for utilization over the period are as follows: Internal Medicine (25.1%), Radiology (21.7%), Rheumatology (17.9%), Family Practice (10.1%), and Endocrinology (9.3%).

CONCLUSION

VFA trends somewhat mirror utilization of DXA since 2005 demonstrating decreasing volumes for most non imaging specialties and increasing volumes for radiology. From 2005 a small absolute increase in DXA study volume relative to VFA is identified.

CLINICAL RELEVANCE/APPLICATION

VFA utilization demonstrates a trend of shifting volumes from non-radiologists to radiologists. VFA aids in the detection of vertebral fractures, (osteoporosis) in patients who may not qualify for treatment based solely on DXA derived BMD/T-scores. It is of growing importance for radiologists to become familiar with VFA indications, reporting standards, and significance in the detection and treatment of osteoporosis.

SSE13-04 Show Me The Money: Practice Patterns of the Top 50 Highest Medicare-Reimbursed Diagnostic Radiologists

pyi10@jhmi.edu

PURPOSE

With the advent of universal health care in the USA, demand for radiological services continue to rise while health care reimbursements decline. The purpose of this study was to examine the 50 diagnostic radiologists who received the most Medicare reimbursements in 2014 and their practice patterns to glean potential solutions for financial viability.

METHOD AND MATERIALS

The Medicare Provider Utilization and Payment Database was queried for the 50 diagnostic radiologists who received the most Medicare reimbursements in 2014. The following were recorded for these radiologists: total reimbursements, total number of patients treated, and distribution of reimbursements amongst types of services rendered. Chi-Squared tests were used to compare reimbursements between radiologists from different US regions.

RESULTS

In 2014, the top 50 Medicare-reimbursed radiologists were paid an average of $1,958,011 (range, $1,247,255 to $5,146,999) for treating an average of 2524 patients (range, 137 to 11,460) and average payment per patient of $3018 (range, $121 to $14,084). 40% of reimbursements came from procedures, 31% from imaging tests, 10% from radiation oncology procedures, and 19% from other services. 80% of radiologists focused the majority of their services to one type of service (e.g., primarily imaging studies), with the remaining 20% having a more balanced mix of imaging studies and procedures. There were even distributions of these radiologists from the Northeast (14; 28%), West (15; 30%), and South (18; 35%) with fewer from the Midwest (3; 6%), although all regions had an average total reimbursement of at least $1,900,000 ($p>0.05$).

CONCLUSION

Even amidst decreasing reimbursements, some radiologists are maintaining very high levels of Medicare payment. Although fewer of these highly-reimbursed radiologists are from the Midwest, overall reimbursements are similar between regions. How these radiologists achieve high levels of reimbursement vary, with most focusing on one service type, e.g., primarily procedures, suggesting that a focused practice may improve overall productivity. Radiologists should be reassured that it is possible to maintain high reimbursement levels in today's healthcare market.

CLINICAL RELEVANCE/APPLICATION

Amidst decreasing reimbursements, some radiologists are able to maintain very high levels of Medicare payment at an average of nearly $2 million.

SSE13-05 How Specialized are Radiologists Who Are Reading MRI Studies of the Brain?

Monday, Nov. 26 3:40PM - 3:50PM Room: S403B

evan.calabrese@ucsf.edu

PURPOSE

To assess the degree of specialization in radiologists who are interpreting MRI studies of the brain.

METHOD AND MATERIALS

The IRB approved this study under exempt review. We accessed the Medicare Physician and Other Supplier Public Use File for calendar year 2015. We searched for all radiologists who interpreted MRI of the brain, neck, and spine (i.e. neuro MRI). Radiologists were sorted by the number of MRI studies interpreted and by percent of fee-for-service Medicare (FFSM) claims derived from interpretation of the associated CPT codes. Based upon the distribution of percent claims from neuro MRI, we sought to identify a group of radiologists who read the fewest numbers of neuro MRI, termed "low volume readers," and the associated percent of all FFSM MREx that are interpreted by these low volume readers. The database was queried with Python. Statistical analysis was performed with Python and Excel.

RESULTS

A total of 13,694 radiologists interpreted 4,066,887 neuro MRIs. Of the radiologists reading FFSM neuro MRI, the average number of studies read was 297 (10th-90th percentile, 46-690) and the average percent of claims dollars arising from neuro MRI was 23% (10th-90th percentile, 6%-56%). The distribution in numbers of MRI interpreted and in percent of claims dollars arising from neuro MRI is shown in Figure 1. Based upon the distributions of radiologist volume and percent revenue from neuro MRI, the threshold for low volume readers was set at 97 FFSM neuro MRI examinations. There were 3,674 radiologists in the low volume group (27% of radiologists interpreting neuro MRI), and these radiologists were responsible for interpreting 207,8144 of 4,066,887 neuro MRI (5% of all neuro MRI).

CONCLUSION

There are large numbers of radiologists who read small numbers of neuro MRI per year. Approximately 27% of radiologists interpreting neuro MRI read fewer than 97 neuro MRI per year, which corresponds to 5% of all neuro MRI studies being interpreted by a low volume radiologist. The composition of this low volume radiologist group, and whether there is a relationship between volume of neuro MRI interpreted and quality of those interpretations, are unknown; these questions should be further studied.

CLINICAL RELEVANCE/APPLICATION

We describe a method for assessing degree of specialization of the radiology workforce. The methods can be used to assess either individual radiology practices, or regional or national samples.

SSE13-06 Qualitative and Quantitative Analysis of Radiologists' Workload in an Academic Hospital Department

Monday, Nov. 26 3:50PM - 4:00PM Room: S403B

Participants
Ulrike Streit, MD, Goettingen, Germany (*Presenter*) Nothing to Disclose
Joachim Lotz, MD, Gottingen, Germany (*Abstract Co-Author*) Nothing to Disclose
Ali Seif Amir Hosseini, MD, Goettingen, Germany (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

Ulrike.Streit@med.uni-goettingen.de

PURPOSE

The role of today's hospital-based radiologists goes far beyond interpretation-related tasks. This observational study defines these types of activities, as well as quantifies the type of value-adding interactions radiologists experience on a daily basis with referring departments and other health personnel. The purpose of this study is to evaluate the quality and quantity of these value-adding non-image interpretation tasks in the daily routine of hospital-based resident and attending radiologists.

RESULTS

Five main categories of responsibilities for NITs were identified including teaching and education, clinical decision support, management and organizing, patient care, and other. For both cross-sectional imaging units, CT and MRI, NITs constituted 50% of the workday for attending radiologists and 48% for resident radiologists. Subcategories revealed heterogeneous results for attendings and residents for each category: teaching and education (14% / 18%), management and organizing (17% / 6%), patient care (7% / 25%), clinical decision support (44% / 24%), and other (18% / 27%).

CONCLUSION

NITs consumed a significant portion of a radiologist's workday, therefore, number of examinations performed is not a reliable surrogate for the daily workload of hospital-based radiologists especially in the cross-sectional imaging units. Though time consuming these non-image interpretation tasks contribute to the already perceived evolving role of a modern radiologist towards central figures in the process of managing patients and patient information, fulfilling a critical role, which surpasses image interpretation-related tasks towards a more integrative and consultative role. These findings will help to further define the changing role of the radiologist to other physicians, non-medical personnel, hospital administrators, as well as policy makers.

METHODS

A prospective, observational study was performed in the department of radiology of a German university hospital. Two experienced radiologists performed a two months observation of the entire medical staff. The observers followed the subject radiologists throughout the workday, recording activities using a time and motion methodology. An evaluation matrix was developed to characterize and quantify image interpretation tasks (IITs) and non-image interpretation tasks (NITs) for resident and attending radiologists.

CONCLUSION

ML technology can be exploited to perform large-scale investigations of CT-tBMD on this and other large cohorts as groundwork for developing CT-based osteoporosis screening.

Background

Opportunistically CT measured vertebral trabecular bone mineral density (CT-tBMD) has been proposed as a possible alternative to DEXA measurements for assessing osteoporosis in cases where a body CT is performed for other motives (trauma, surgery, oncology, COPD, etc). Such an application will require better understanding of CT-tBMD ranges in health and pathology. Previous works, using traditional semi-automatic quantization methods, have been of limited cohort size. Recent developments in machine learning (ML) applied to analyze medical imaging data have increased robustness and accuracy enabling accurate automated segmentation of anatomic structures. We applied a ML pipeline to a large public cohort containing CT and correlated clinical data (COPDgene.org) to demonstrate the viability of using such technology for large-scale tBMD studies.

Evaluation

Deep Reinforcement Learning and Adversarial Deep Image-to-Image ML networks were trained with 4560 manually segmented vertebrae from 380 CTs. A pipeline incorporating this network and 5% erosion algorithm, for trabecular bone isolation, was developed. It showed a 4.5% prediction error when tested on another 834 manually segmented vertebrae. The pipeline was applied to 9554 chest CTs from the COPDGene cohort and correlated to available corresponding clinical data. Results demonstrate a downward trend of BMD with age with slightly more rapid decline in later years for women than men. The data demonstrated significantly lower BMD in subjects diagnosed with osteoporosis, with history of compression or hip fracture (p-values<0.01). Processing time was 5.9 sec per series on a 3 GPU workstation.

Discussion

These findings agree with previous ones obtained by traditional semi-automatic techniques on smaller cohorts. Novelty in this work is the use of an ML based and fully automatic pipeline which provides precision and scalability and permits rapid application to the current and other large cohorts.

SSE14-02 Towards Hierarchical Optimization of Pretrained Deep Learning Models for Tuberculosis Screening in Chest Radiograph

CONCLUSION

We verified that hierarchical optimization process could assist to optimize the pretrained deep learning models by developing and incorporating hierarchical and structured feature information.

Background

Tuberculosis (TB) is a chronic infectious disease and thus early screening is critical in alleviating its transmission and reducing reproductive rate. While there are a few researches for the given task in chest radiograph through developing new deep learning models and simply using fixed pretrained models, there are very rare researches on further optimizing pretrained models to improve the performance.

Evaluation

We focused on optimizing pretrained models using hierarchical optimization process using iterative adaptive fixation and release operations and parallel model building. Based on the implications of high-level abstractions, lower layers in pretrained models will have more general feature information (e.g., edges) and upper layers keep domain-specific feature information (e.g., object parts or objects). The optimization is done by making a parallel pool consisting of 10 instances of a pretrained deep learning model and by bypassing through fixation/release of convolution layers with slightly perturbed feature information and then fine-tuning is repeatedly done until the gradient changes become negligible. Finally, the winner will be selected as the best model. We used 7,000 normal patients' chest radiograph images, and 7,000 TB patients' images for training using the hierarchical optimization. As the pretrained models, we used GoogLeNet, ResNet-152 and Inception-ResNet-V2. For validation and test, we used two independent datasets each consisting of 300 normal patients' images and 150 TB patients' images. Results showed that the area under the receiver operating characteristics curves (AUCs) of GoogLeNet, ResNet-152 and Inception-ResNet-V2 were 0.97, 0.99 and 0.99, respectively. For comparison, the AUCs of the models without such optimization process obtained 0.89, 0.93, 0.92, respectively.

Discussion

We proposed a method of optimizing pretrained deep learning models in a hierachical manner. Further study is required to deal with class-imbalanced dataset issues.

SSE14-03 Understanding Deep Learning: Insights from a Classifier Trained to Predict Contrast Enhanced Phase from Abdominal CT Imaging

Monday, Nov. 26 3:20PM - 3:30PM Room: E353C

CONCLUSION

The data that we report here demonstrates that voxel level visualizations provide powerful insight into the precise anatomical regions of imaging which activate a network. Investigating the anatomical structures identified in these maps may provide key insight for systems (e.g., tumor) where well performing deep learning models exist but defining radiological signatures are unknown.

Background

The imaging features identified by deep learning classifiers are difficult to describe directly. Deep learning classifiers learn to identify images by optimizing a series of non-linear functions to activate on texture and shapes. The effect of this, is that for a given multi-layer network, multiple visually different inputs can act to strongly activate a network's output. Multiple techniques (attention maps, grad-cam maps, saliency maps, guided backpropagation maps, and saliency-attention maps) have been purported to provide insight as to the specific imaging features identified by a deep learning model. We directly investigated the utility of these methods in a radiology context.

Evaluation

Typical organ enhancement patterns that follow vascular contrast agent administration are well understood. We leveraged this and developed a deep learning classifier to identify contrast enhanced renal scan phase from whole slice CT data. The classifier exceeded 90% accuracy on the test set. We utilized this classifier to explore the utility of attention maps, grad-cam maps, saliency maps, guided backpropagation maps, and saliency-attention maps to identify the imaging features our model utilized to predict scan phase.

Discussion

Saliency maps and guided back propagation maps identify voxels in input imaging which promote model prediction. For most scans these visualizations identified similar anatomical regions which directly reflect renal scan phase (renal: cortex, medulla, artery, vein, aorta, and vene cava). Attention maps, grad-cam maps, and saliency-attention maps illustrate layer activations and indirectly identifed the anatomy responsible for these activations. As a whole, these maps indicated that the kidneys were responsible classification but could not clearly localize the features.

PURPOSE

DICOM header information is frequently used to classify image types within the clinical radiological workflow, however, if a header contains incorrect or missing fields, it cannot be reliably used for classification. To expedite image transfer and interpretation, we trained a convolutional neural network in the task of classifying chest radiographs into 4 categories: AP/PA images, lateral images, soft tissue images and bone images (for dual energy studies).

METHOD AND MATERIALS

Our research included 5669 clinical thoracic radiographs. One set of 1911 radiographs, acquired Feb. 2006 to Feb. 2017, was manually sorted into the four categories. The manually sorted set consisted of 818 AP/PA images, 419 lateral images, 389 soft tissue images, and 285 bone images. Classifying the images using DICOM header information alone left 38% unclassified. Using TensorFlow (Google, 2015), an AlexNet architecture network was trained from scratch, in which 1242 images (65%) were used for training, 382 images (20%) for validation, and 287 images (15%) for testing. Next, the trained network was applied to an independent set of 3758 additional images yielding 68 (1.8%) images misclassified, 65% of which were soft tissue and AP/PA images.

RESULTS

The network classified Images with a high accuracy (98.19%). An important task for clinical workflow is the distinction between an AP/PA and its associated lateral view to ensure correct organization of the imaging sequence as well as appropriate image processing and CAD application. The AUC for distinguishing between AP/PA and lateral was 0.9998 ± 0.0002. Other results included AUC=0.9979 ± 0.0005 in distinguishing between soft tissue and AP/PA images and AUC=1 in distinguishing between soft tissue and bone images. In addition to high performance, the rapid classification of images could be applied in a hospital setting without disruption of clinical workflow. The model was trained in 5 min and classified 3758 images in 3 min. By comparison, an experienced human sorter took about 11.6 hours to classify the test set.

CONCLUSION

A trained convolutional neural network can classify different radiographic projections from the same study, most notably AP/PA vs. lateral, with high speed and accuracy.

CLINICAL RELEVANCE/APPLICATION

A trained neural network can be used in a clinical setting to quickly and accurately classify radiographs by image type to ensure correct organization of the study sequence.

SSE14-05 Deep-Learning Renal Segmentation for Fully Automated Radiation Dose Estimation in Radionuclide Therapy

Monday, Nov. 26 3:40PM - 3:50PM Room: E353C

Price.Jackson@petermac.org

PURPOSE

Convolutional neural networks have been shown to be powerful tools to assist with object detection and, like a human observer, may be trained based on a relatively small cohort of reference subjects. Rapid, accurate organ recognition in medical imaging permits a variety of new quantitative diagnostic techniques. In the case of therapy with targeted radionuclides, it may permit

comprehensive radiation dose analysis in a manner that would often be prohibitively time-consuming using conventional methods.

METHOD AND MATERIALS

An automated image segmentation tool was developed based on 3-dimensional convolutional neural networks to detect right and left kidney contours on low-dose, non-contrast CT images. The model training set involved 89 manually-contoured cases and was then tested on a cohort of 24 patients receiving therapy with 177Lu-PSMA-617 for metastatic prostate cancer. Automatically generated contours were compared with those drawn by expert and assessed for similarity based on dice score, mean distance-to-agreement and total segmented volume. Further, the contours were applied to voxel dose maps computed from post-treatment quantitative SPECT imaging and renal dose estimates using automated and manual means were evaluated for statistical bias.

RESULTS

Neural network segmentation was able to identify right and left kidneys in all patients with a high degree of accuracy. Mean dice score was 0.91±0.05 and 0.86±0.18 for right and left kidneys, respectively, with associated mean distances-to-agreement of 2.0±1.0 and 4.0±7.5 millimetres. The system was integrated into the hospital image database, returning contours for a selected study in approximately 90 seconds. Poor performance was observed in 3 patients with cystic kidneys of which only few were included in the training data. Mean radiation absorbed dose based on automated contours was within 4.0% of that computed with manual segmentation.

CONCLUSION

Automated contouring using convolutional neural networks shows promise in providing quantitative assessment of functional SPECT and PET images; in this case demonstrating comparable accuracy for radiation dose interpretation in radionuclide therapy relative to a human observer.

CLINICAL RELEVANCE/APPLICATION

The primary application of this research is quantitative diagnosis and improved nuclear medicine treatment personalisation.

SSE14-06 Using Active Learning and Domain Adaptation to Train a 3D-Unet for Liver Segmentation at a High Volume Liver Transplant Center

Monday, Nov. 26 3:50PM - 4:00PM Room: E353C

brett.marinelli@gmail.com

PURPOSE

To demonstrate the ability of a deep learning model to automatically assess liver volume utilizing publicly available data and active learning that successfully transfers to an external cohort at a high volume transplant center.

METHOD AND MATERIALS

131 CTs and liver segmentations were used from the MICCAI Grand Challenge LiTS dataset. 257 clinically acquired CTs (CACs) were collected from an institution's PACs where liver volumetry was recorded. CACs are from between 1/2014 - 12/2016 and include145 pre-transplant evaluations (56%), 159 cirrhotics (62%), 92 hepatocellular carcinoma cases (36%), and 18 prospective living liver transplant donors (7.0%). A preprocessing pipeline standardized all images to 128x128x128 voxels. As a benchmark, a 3D-UNet convolutional neural network (CNN) was trained on an 80/20 train/validation split of the LiTS dataset. Then, a 3D-UNet was fit to a training set composed of the LiTS dataset augmented by six copies of five CACs in an active learning framework. A semi-automatic GrowCut method was used for segmentation of active learning cases with Slicer3D. The CAC dataset excluding active learning scans was used as the comparative test set. Dice similarity validation scores were recorded. Successful volume measurement was defined as a difference within 200cc. Median and 1st-3rd interquartile range (IQR) were reported for both tested models. A paired student's t-test compared performance before and after implementation of active learning.

RESULTS

The benchmark model demonstrated a 0.90 Dice on the LiTS validation set, successful volume measurements in 139/257 livers and median absolute difference of 180 mL (IQR 80-311 mL) in the test set. The active learning approach demonstrated a 0.84 Dice on the LiTS validation cohort, successful volume measurements in 150/252 livers and a median absolute difference of 160 mL (IQR 67-313mL). The active learning approach yielded superior results (P=0.04).

CONCLUSION

Combining active learning and domain adaptation for liver segmentation can significantly improve model performance at capturing liver volumes utilizing publicly available datasets while deploying the model at a high volume liver transplant center.

CLINICAL RELEVANCE/APPLICATION

We describe methods that use a deep learning model for automatically assessing liver volume with publicly available data and active learning that successfully transfers to an external cohort at a high volume transplant center.

PURPOSE

To describe the normal motion pattern of the scaphotrapezial joint (STJ) and capitate-triquetrum interval (CTI) during active radial and ulnar deviation of the wrist during dynamic MRI, and to determine the observer performance of measurements in asymptomatic volunteers.

METHOD AND MATERIALS

In this prospective study, real-time 3T MRI examinations were performed in 35 wrists (19 asymptomatic volunteers; age mean: 30.5 yrs [range: 20-55]; M/F:10/9). Using a radial fast-GRE coronal sequence with 315 ms temporal resolution and a total acquisition time of ~ 20 seconds, 60 images were acquired during continuous imaging of the moving wrist through the full range of motion from radial to ulnar deviation. Two independent readers measured 1) the transverse translation of the trapezium at the STJ and 2) the CTI. A two-sample Kolmogorov-Smirnov goodness-of-fit hypothesis test was performed to evaluate the relationship between these measurements with laterality (right vs. left), sex, lunate type, and wrist kinematic pattern (row vs. column kinematics). Intra-observer and inter-observer correlation coefficients were determined.

RESULTS

Translation of the trapezium at the STJ in neutral, radial, and ulnar deviation averaged 0.3±0.8 mm, 1.9±1.2 mm, and -0.4±1.0 mm, respectively. There was no significant difference in trapezium translation with wrist laterality, sex, lunate type, or wrist kinematic pattern. The CTI in neutral, radial, and ulnar deviation averaged 5.3±1.4 mm, 3.6±1.1 mm, and 6.0±1.4 mm, respectively. The mean CTI was greater in men than women in the neutral position only (p=0.019). The mean CTI was increased in wrists with type II lunates compared to type I lunates during radial (p=0.001) and ulnar deviation (p=0.014). There was no difference in CTI with wrist laterality or wrist kinematic pattern. Mean intraobserver and interobserver correlation coefficient was 0.79 and 0.77, respectively.

CONCLUSION

Using dynamic MRI, this study provides a normal range of expected STJ and CTI measurements in asymptomatic wrists. Dynamic MRI with a short acquisition time may be used as a supplement to conventional static MRI in the diagnostic evaluation of the midcarpal compartment.

CLINICAL RELEVANCE/APPLICATION

Understanding midcarpal motion patterns is a key step in efforts to establish an accurate diagnosis and promote optimized treatment regimes including nonoperative rehabilitation and surgical planning.

SSE15-02 Distal Radioulnar Joint MR Arthrography for Diagnosing Foveal Tear of Triangular Fibrocartilage: Comparison of MR imaging and MR Arthrography with Arthroscopic Correlation

Monday, Nov. 26 3:10PM - 3:20PM Room: N228

Participants
Sung Tae Hwang, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

Kyung-Sik Ahn, MD, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Chang Ho Kang, MD, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

Baek Hyun Kim, MD, Ansan, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Euddeum Shim, Ansan, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the value of distal radioulnar joint (DRUJ) MR arthrography for diagnosing foveal tear of triangular fibrocartilage (TFC).

METHOD AND MATERIALS

A total of 83 patients (54 men, 29 women; mean age, 32.7 years) who underwent DRUJ MR arthrography and arthroscopy were retrospectively reviewed. MR protocol includes pre-injection T2- and T1-weighted coronal images and post-injection T2-weighted coronal and T1-weighted fat suppressed coronal, sagittal, and axial images. Two radiologists graded the foveal lamina of the TFC as normal, partial tear, or complete tear after the review of pre-injection image sets and post-injection image sets separately. Diagnostic performance of MR imaging and MR arthrography was assessed based on the arthroscopic findings and compared by using McNemar test.

RESULTS

On arthroscopy, 71 of 83 patients had foveal tear of TFC; 51 cases were isolated foveal tear and 20 cases were combined foveal and styloid tear. On the review of MR images, the sensitivity, specificity, and accuracy for diagnosing foveal tear were 62.0%, 41.7%, and 59.0%. In MR arthrography, the values were 94.4%, 41.7%, and 86.7%, respectively. Sensitivity was significantly higher in DRUJ MR arthrography ($P < .001$).

CONCLUSION

DRUJ MR arthrography increase the accuracy for diagnosing foveal tear of TFC compared to standard MR imaging. The benefit of pre-injection images was minimal in diagnosing foveal tear of TFC.

CLINICAL RELEVANCE/APPLICATION

DRUJ MR arthrography increase the accuracy for diagnosing foveal tear of TFC compared to standard MR imaging.

SSE15-03 Bennett Lesions in Overhead Throwers and Associated Shoulder Abnormalities on MRI

Monday, Nov. 26 3:20PM - 3:30PM Room: N228

Jenika Karcich, MD, New York, NY (*Presenter*) Nothing to Disclose
Jonathan K. Kazam, MD, New York, NY (*Abstract Co-Author*) Nothing to Disclose
Michael J. Rasiej, MD, New York, NY (*Abstract Co-Author*) Nothing to Disclose
Tony T. Wong, MD, New York, NY (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

jek9125@nyp.org

PURPOSE

To determine if the presence of a Bennett lesion in overhead throwers is associated with additional shoulder abnormalities on MRI.

METHOD AND MATERIALS

An IRB approved retrospective review of our database from 1/2012 to 4/2018 identified 35 overhead throwers with a Bennett lesion on MRI. An additional control group consisting of 35 overhead throwers without a Bennett lesion were matched for age, level of play (professional vs. non-professional), and type of study (arthrogram vs. non-arthrogram). Each study was assessed independently by 2 MSK fellowship trained radiologists. The sizes of the Bennett lesions were measured. Each MRI was assessed for the presence of a labral tear, posterior glenoid cartilage deficiency, humeral head notching/cysts, and posterior supraspinatus/infraspinatus tendon fraying or tear. Discrepancies were adjudicated by a third MSK fellowship trained radiologist. Statistical analysis was performed with a chi-squared test.

RESULTS

Average Bennett lesion volume in a professional vs. non-professional overhead thrower: 708 mm3 vs. 545 mm3 (p=0.43). Total Bennett lesions resected: 6% (2/35) Associated MRI abnormalities in Bennett vs. Non-Bennett overhead throwers: SLAP tear: 51% vs. 31% (p = 0.09) Posterior labral tear: 51% vs. 31% (p=0.09) Anteroinferior labral tear: 26% vs. 17% (p=0.38) Posterior glenoid cartilage abnormality (fissure, delamination, partial/full thickness): 23% vs. 3% (p = 0.01) Humeral head notching/cysts: 77% vs. 63% (p = 0.19) Articular surface rotator cuff fraying/tear: 26% vs. 17% (p = 0.38)

CONCLUSION

Overhead throwers with Bennett lesions have an increased frequency of posterior glenoid cartilage abnormalities, but not labral tears or findings of internal impingement.

CLINICAL RELEVANCE/APPLICATION

The presence of a Bennett lesion in an overhead thrower warrants close examination for an adjacent posterior glenoid cartilage abnormality.

SSE15-04 Comparison Between High-Resolution Isotropic Three-Dimensional Cube FS PD and Conventional Two-Dimensional FS PD MR Images of the TFCC at 3 Tesla

Monday, Nov. 26 3:30PM - 3:40PM Room: N228

Participants

For information about this presentation, contact:

1424125302@qq.com

PURPOSE

To compare a newly developed high-resolution isotropic 3D Cube FS PD sequence with conventional high-resolution sequences in assessing TFCC of the wrist in term of image quality and diagnostic performance.

METHOD AND MATERIALS

12 volunteers were enrolled in the study with an average age 22.7 years (range 22-27 years). All the sequences were carried out on all volunteers at 3.0T MR scanner (Signa HDxt, GE Healthcare, Milwaukee, WI) and a Wrist Array coil. Each imaging was performed with 2D PD FS(coronal,axial and sagittal:TR=2900ms,,TE=32.0ms,Matrix=320×256, FOV=10×7cm2, Slicethickness =2.0mm,gap=0.3mm,NEX=2,acquisition,time=99s)and 3D isotropic PD FS (coronal:TR=1400ms, TE=36.4,Matrix=256×256, FOV=10×9cm2, Slicethickness=0.4mm, gap=-0.2mm, NEX=0.5, acquisition time=279s).Delineation of anatomic structures of the wrist, amount of artifact, effect of fat suppression, image blur, and overall quality were qualitatively evaluated using the 5-point scoring system(5: excellent, 4: good,3: satisfactory, 2: poor, and 1: nonidentified.Signal-to-noise-ratios (SNR) of each structure and contrast-to-noise ratios(CNR)between structures of the TFCC were quantitatively measured using vendor supplied software (AW4.6work station, GE).

RESULTS

The 2D MRI demonstrated higher scores than 3D in anatomic structure of the SL ligament(P=0.043), the LT ligament(P=0.022),cartilage(P=0.043),artifact(p=0.007)and image blur(p=0.015).However,there were no statistical significance between 2D and 3D MRI in disc and overall quality. Higher SNR values were found for in the 2D sequence (6.32±3.32)than the 3D(4.20±1.66),The corresponding CNR values were(4.87±3.10) for the 2D and(3.45±1.97) for the 3D.To better control for voxel size, we also measured the SNR and CNR values in the reconstructed 2-mm images from original 3D isotropic images and obtained similar values as in the 2D (5.86±3.05 and 3.01±0.86, respectively), indicating that reconstruction with larger slice thickness improved SNR and CNR.

CONCLUSION

Although,Isotropic 3D Cube FS PD sequence may enhance standard wrist MRI by increased visualization of multiplanar and post processing capabilities, however,the 3D Cube image quality was lower.

CLINICAL RELEVANCE/APPLICATION

With regard to clinical applications,3D Cube image of the wrist has almost equal potential to 2D MRI.

SSE15-05 Correlation Between Fat Fraction, Cross Sectional Area of Rotator Cuff and Muscle Strength: Using MRI DIXON Sequence and Biodex Isokinetic Test

Monday, Nov. 26 3:40PM - 3:50PM Room: N228

Participants
Sung Tae Hwang, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose
Chang Ho Kang, MD, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Kyung-Sik Ahn, MD, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

Suk-Joo Hong, MD, Rochester, MN (*Abstract Co-Author*) Nothing to Disclose
Baek Hyun Kim, MD, Ansan, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Euddeum Shim, Ansan, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the correlation between fat fraction (FF), cross sectional area (CSA) of rotator cuff and muscle strength using T2-weighted Dixon Spin-Echo Fat image and biodex isokinetic test.

METHOD AND MATERIALS

37 patients (13 men, 24 women; age range, 45-78 years) undergoing shoulder MR imaging with concomitant biodex isokinetic test were enrolled in this study. Quantitative fat analysis and CSA measurement of rotator cuff (supraspinatus [SS], infraspinatus [IS], teres minor [TM]) in the image plane of scapular Y-shape were performed by one musculoskeletal radiologist using a post-processing software (Syngo via, Siemens healthineers, Erlangen, Germany) for T2-weighted Dixon Spin-Echo fat image. Multivariate regression and multiple linear regression analysis were used to investigate the relationship between 4 biodex isokinetic test parameters (peak torque [PT], peak torque/body weight [BW], torque at 30° [T30], total work [TW]) for 8 shoulder movements (60°, 180° flexion [FL] and extension [EX], 60°, 180° internal rotation [IR] and external rotation [ER]) and FF and CSA of the rotator cuff.

RESULTS

Multiple linear regression analysis shows significant correlation between CSA of SS and T30, TW of 180° ER; PT, T30, TW of 60° IR; PT, T30, TW of 180° IR, and between CSA of IS and T30 of 60° IR; PT, BW, TW of 180° ER (all $p<=0.04$). A significant correlation between FF of IS with all parameters of 180° IR and 180° ER, and between CSA of IS with all parameters of 180° IR was found on multivariate regression analysis (all $p<=0.04$). FF of TM was significantly associated with PT, T30, TW of 60° IR ($p<=0.03$). There was no significant correlation between CSA and FF of rotator cuff and parameters of FL and EX, whereas age and sex were significantly associated with parameters of FL and EX, as well as with some parameters of ER and IR (all $p<=0.05$).

CONCLUSION

CSA and FF of SS and IS measured on T2-weighted Dixon Spin-Echo Fat image correlated with the strength of shoulder movements, especially IR and ER. Therefore, the strength of rotator cuff could be more elaborately evaluated by measuring both FF and CSA of the muscles.

CLINICAL RELEVANCE/APPLICATION

CSA measurements and fat quantification using DIXON have the potential to become an important clinical resource when evaluating the muscles of the rotator cuff.

SSE15-06 Intra and Inter Observer Variability among Different Methods of Measuring Carpal Collapse

dr.muhil@gmail@gmail.com

PURPOSE

To find out that the method with least intraobserver and interobserver variability among different methods used for determining carpal collapse.

METHOD AND MATERIALS

Retrospective radiographic evaluation of 50 normal wrist PA radiographs were done by 3 observers, measuring normitative values of Carpal height ratio (CHR), Revised Carpal Height Ratio (RCH ratio), Capitate radius (CR index). 1) Carpal Height Ratio (CHR) measured by carpal height divided by the length of 3rd metacarpal. 2) Revised Carpal Height Ratio (RCH ratio) measured by dividing the carpal height by the length of capitate. 3) Capitate radius (CR index) measured by closest distance between the distal edge of radius and the proximal edge of capitate. The measurements were repeated after one month by all the observers. Data was collected and statistical analysis was done by using SPSS 21 version. Data from all the observers were was described in descriptive terms with mean and standard deviation. For intra observer variability, correlation coefficient was calculated for every individual observer. For inter observer variability intraclass correlation coefficient was calculated and presented with r and p value.

RESULTS

Total of 50 normal wrist PA radiographs (17 females and 33 males) were studied between the age 13 to 71 years with mean age of 37.52 years. The mean range of values in our study for CHR was 0.49 ± .03to .51 ±.03; RCHR 1.51 ± .077 to 1.57 ± .059 and CRI 0.972 ± .09 to 1.06 ± .12. The r value was close to 0.91 and p value was <0.001 in all the three observers in CR Index meaning that the intra observer variability was least in CR Index. For the inter observer variability Intra Class Coefficient of 0.9 indicates that the CR Index has the least variability. RCH Ratio has the maximum variability in both inter and intra observer comparisions

CONCLUSION

We conclude that CR Index is the best method to measure carpal collapse in terms of reproducibility of the results.

CLINICAL RELEVANCE/APPLICATION

With regard to intra and inter observervariability, CR Index was most reliable measurement for carpal collapse, as only one measurement is taken in CR index and the measurement points are well defined.

PURPOSE

To compare fully sampled slice-encoding for metal artifact correction (SEMAC) and vastly undersampled compresses sensing-(CS)-SEMAC sequences for metal artifact reduction MRI in patients with total hip arthroplasty (THA).

METHOD AND MATERIALS

Following internal review board approval and informed consent, 30 patients with pain and dysfunction following THA underwent prospectively 1.5 T MRI, including coronal intermediated-weighted (IW)- and short tau inversion recovery (STIR) SEMAC (22:39 min) and CS-SEMAC (9:55 min) pulse sequences with otherwise identical parameters. Following anonymization and randomization, two fellowship-trained musculoskeletal radiologists independently evaluated the datasets. Outcome variables included image quality parameters, bone implant interface visibility, overall reader satisfaction, detection rate of abnormalities of the hip joint. Statistical analysis included kappa statistics and paired rank sum tests. P-values <= 0.05 were considered significant.

RESULTS

The inter-observer agreements were at least adequate for all categories (kappa > 0.58). There was no significant difference for the technical parameters, including motion (p = 0.69), blur (p = 0.37), noise (p = 0.06), metal artifact reduction (p = 0.46), tissue contrast (p = 0.81), and fat-suppression (p > 0.99). The visibility of bone implant interface of the acetabular and femoral component was rated on average as "good" indicting minimal impairment with preservation of all structural details without significant differences between SEMAC and CS-SEMAC (p = 0.51). The overall reader satisfaction was "good" for both SEMAC and CS-SEMAC (p=0.85). For SEMAC versus CS-SEMAC, readers found an average of 18 versus 18 osteolyses (p = 0.87), 15 versus 17 cases of synovitis (p = 0.38), 23 versus 21 peritorchanteric fluid accumulations (p = 0.55) and 23 versus 19 abductor tendon tears (p = 0.34), respectively.

CONCLUSION

In patients with painful hip arthroplasty implants, fully sampled and vastly undersampled SEMAC pulse sequences produce similar image quality and afford similar detection rates of abnormalities.

CLINICAL RELEVANCE/APPLICATION

The vastly undersampled CS-SEMAC technique allows for 55% faster MRI of THA implants, thereby preserving the detection rates of abnormalities, when compared to fully sampled SEMAC technique.

SSE16-02 SEMAC-VAT MR Imaging at 1.5 T in Patients with Pedicle Screw Fixation: Is It Superior to Standard MR Imaging for the Detection of Postoperative Complications?

Monday, Nov. 26 3:10PM - 3:20PM Room: N227B

PURPOSE

To compare the Slice-encoding metal artifact correction (SEMAC)-View-angle tilting (VAT) sequence with the standard turbo-spin echo (TSE) MR sequence for image quality, visibility of periprosthetic structures, and diagnostic confidence for detection of postoperative complications in patients with pedicle screw fixation at 1.5 T.

METHOD AND MATERIALS

Seventy patients with pedicle screw fixation between the thoracic vertebrae and the sacrum were included. SEMAC-VAT imaging were compared with standard TSE images. The MR imaging were retrospectively evaluated by two radiologists for SNR (signal-to-noise ratio) of anatomical structures and size of artifacts, visibility of periprosthetic anatomical structures, and diagnostic confidence for detection of postoperative complications. Paired t-tests and Wilcoxon signed-rank tests were used for comparisons, and intra-class correlation and kappa values were used for inter-observer agreement.

RESULTS

For all anatomical structures, the signal-to-noise ratio was significantly lower for SEMAC-VAT than for TSE images ($p < 0.001$). SEMAC-VAT images demonstrated effective artifact reduction compared to TSE images ($p < 0.001$). The visibility of most periprosthetic anatomical structures, and diagnostic confidence for detection of postoperative complications, were better for SEMAC-VAT than for TSE imaging ($p < 0.001$). For the spinal canal, however, TSE was better ($p < 0.001$).

CONCLUSION

MR images with SEMAC-VAT can significantly reduce metal artifact, providing improved delineation of periprosthetic anatomical structures and diagnostic confidence for detection of postoperative complication compared with standard TSE images. For the spinal canal, however, TSE was better.

CLINICAL RELEVANCE/APPLICATION

Taking into account the results of our own, we propose the following guidelines for performing SEMAC-VAT image on patients with pedicle screw fixation.

SSE16-03 Metal Artifact Reduction on Photon-Counting-Detector CT Using Tin Filtration and Detection of High-Energy Photons

PURPOSE

To evaluate the use of photon-counting-detector CT with tin filtration (PCD-CT Sn) to improve diagnosis in patients with orthopedic metal implants.

METHOD AND MATERIALS

Adult patients with orthopedic metal implants underwent CT using commercial energy-integrating-detector CT (EID-CT) followed by PCD-CT Sn (140 kV, 0.4 mm Sn, energy thresholds of 25 and 75 keV). EID-CT and PCT-CT Sn Bin 2 (75 - 140 keV) 2-mm images were reconstructed. Three radiologists blindly evaluated images in a side-by-side fashion, comparing predefined anatomic structures using a 6-point scale (0 = critical structures totally obscured to 5 = anatomic recognition with high confidence in diagnosis). Preference for PCD-CT Sn was assessed using a 5 point scale (-2= decline in confidence; 0= no difference; +2= improvement in diagnostic confidence). The effect of artifact on the ability to make a diagnosis was also graded (1= artifact has no/minimal effect to 3= artifact impedes diagnosis), with quantitative analysis measuring the width of most prominent artifact at the axial plane. Statistical analysis was performed using the Wilcoxon signed rank test, where $p<0.05$ was considered statistically significant.

RESULTS

20 patients with orthopedic metal implants were included in the study, with hardware in the spine in 12 patients, shoulder in 3, and extremities in 5. The mean overall visualization scores of the cortex, trabeculae, and implant-trabecular interface were significantly better for PCT-CT Sn (4.4. vs. 3.3, $p<0.0001$). For spinal hardware, PCD-CT Sn showed improved image quality score for the central canal (3.3 v 0.9, $p<0.0001$), with similar findings for neural foramina. The mean overall preference score for PCT-CT Sn was $+1.6 \pm 0.7$ compared to EID ($p<.0001$), indicating improved diagnostic confidence. The effects of metal artifact on diagnosis were

less at PCD-CT Sn (1.9 v 2.6, p<0.0001), and the width of the metal artifact was substantially reduced (from 1.1 ± 1.4 cm to 0.5 ± 0.5 cm, p<0.0001).

CONCLUSION

Selection of high-energy photons using a Sn filter and PCD-CT bin 2 images markedly improves visualization of key anatomic structures and improves diagnostic confidence by reducing the size of metal-related artifacts.

CLINICAL RELEVANCE/APPLICATION

PCD-CT with tin filtration and reconstruction of images obtained using high-energy photons provides additional critical diagnostic information compared to commercial EID-CT systems to patients with metal implants.

SSE16-04 Utility of CT Metal Artifact Reduction Algorithms for Intervertebral Devices: Experimental Study in Ex Vivo Bovine Coccyx Using Micro-CT as the Reference Standard

PURPOSE

The accuracy of radiological assessments of bony fusion following spinal fusion is affected by radiographic interference from metallic components of the intervertebral devices. Therefore, this study evaluated the utility of dedicated CT metal artifact reduction algorithms (SEMAR and MAR) for measuring trabecular bone microarchitecture in a comparison using micro-CT as the gold standard.

METHOD AND MATERIALS

Twenty bovine coccyges with and without titanium or poly-ether-ether-ketone (PEEK) interbody devices were scanned by ultra-high resolution MDCT (Aquilion Precision, SEMAR), 256-MDCT (Revolution CT, MAR), and micro-CT as the gold standard. The quality of the MDCT images was evaluated in terms of the visibility of trabecular bone using a 3-point Likert scale. Trabecular thickness (Tb.Th), trabecular number (Tb.N), trabecular separation (Tb.Sp), fractal dimension (FD), and volumetric bone mineral density (vBMD) of the same 10-mm-thick portion of coccyx including a metal artifact were obtained for MDCTs and micro-CT. Relationships between MDCT- and micro-CT-derived trabecular bone indices were compared.

RESULTS

The mean reduction in the width of the artifact was 48.7% for SEMAR/titanium, 20.6% for SEMAR/PEEK, 15.8% for MAR/titanium, and 18.9% for MAR/PEEK. The image quality analysis revealed that the artifact was removed from the trabecular bone space in 72.7% of the SEMAR/titanium images and 18.2% of the images obtained using the three other combinations. FD, Tb.Th, Tb.Sp, and vBMD measured by ultra-high resolution MDCT were found to be significantly correlated with micro-CT values (ρ=0.486~0.499, p=<0.001~0.05) while no significant correlation was observed between 256-MDCT- and micro-CT values. For coccyx with titanium, the correlations of Tb.Th, Tb.Sp, and vBMD with micro-CT values were improved by SEMAR (ρ=0.491~0.489, p=<0.001~0.05). For coccyx with PEEK, correlations of FD, Tb.Sp, and vBMD with micro-CT values were improved by SEMAR (ρ=0.502~0.525, p=<0.001~0.05).

CONCLUSION

SEMAR combined with ultra-high resolution MDCT objectively and subjectively decreases metal artifacts when compared to 256-MDCT with MAR. Correlations of trabecular indices and vBMD with micro-CT values were improved with SEMAR.

CLINICAL RELEVANCE/APPLICATION

Trabecular bone architecture can be assessed using ultra-high resolution MDCT with a metal artifact reduction algorithm, suggesting that it is possible to evaluate bony fusion after spinal fusion.

SSE16-05 Combined Iterative Metal Artifact Reduction Reconstruction and Virtual Monoenergetic Extrapolation at Higher Photon Energies in CT Imaging of Ankle Arthroplasty Implants

PURPOSE

To compare the effects of combined virtual monoenergetic extrapolation (VME) and iterative metal artifact reduction (iMAR) at higher photon energies on low and high-density metal artifacts and overall image quality.

METHOD AND MATERIALS

Six total ankle arthroplasties were implanted into human cadaveric ankles and underwent computed tomography with a dual-source scanner at tube voltages of 80 and tin-filtered 150 kVp to produce mixed 120 kVp equivalent polychromatic images. Image datasets were created with six protocols including polychromatic weighted filtered back projection (WFBP), polychromatic iMAR, monoenergetic WFBP at 150 and 190 keV, and monoenergetic iMAR at 150 and 190 keV. High- and low-density artifacts were separately quantified with a threshold-based MATLAB script. After anonymization and randomization, two observers independently ranked the datasets for overall image quality. A conservative p-value of less than 0.001 was considered significant for all statistical analyses.

RESULTS

Least amount of high-density artifacts were visualized with iMAR 190 keV and iMAR 150 keV (all p-values < 0.001), whereas polychromatic iMAR was the most effective method of mitigating low-density streaks (p-values < 0.001). For both low and high-density artifacts, polychromatic iMAR acquisition was superior to WFBP 150 keV and WFBP 190 keV (p-values < 0.001). Readers ranked the overall image quality of polychromatic iMAR images highest on sharp kernel reconstructions (p-values < 0.001). Similarly, on soft tissue kernel reconstructions, the polychromatic iMAR images were ranked the highest with a statistically significant difference over other techniques (p-values < 0.001), except for iMAR 150 keV (p = 0.356).

CONCLUSION

iMAR with polychromatic spectra and VME result in fewer metal artifacts and better image quality than WFBP with polychromatic spectra and VME. The combination of iMAR and VME at higher photon energies results in mixed effects on implant-induced metal artifacts, including decreasing high-density artifacts and increasing low-density artifacts, which in combination may not improve image quality for a particular implant when compared to polychromatic iMAR images at lower photon energies.

CLINICAL RELEVANCE/APPLICATION

Combined iMAR and VME at higher photon energies results in mixed effects on metal-related artifacts, which overall may not improve image quality for a particular implant.

PURPOSE

To identify an optimal imaging protocol for metal artifact reduced MRI by application of different post-processing parameters in compressed sensing slice-encoding for metal artifact correction (CS-SEMAC).

METHOD AND MATERIALS

In an experimental setup, a total hip arthroplasty (THA) embedded in gadolinium containing agarose was scanned at 1.5T. Pulse sequences included coronal STIR, T1w and T2w CS-SEMAC sequences. All pulse sequences were acquired with 11, 19 and 27 slice-encoding steps (SES). Post-processing was performed with variations of the parameters (i) number of iterations (5, 10, 20, 30, 50) and (ii) normalization factor (0.0005, 0.001, 0.002, 0.003, 0.005). Following, identical STIR, T1w and T2w pulse sequences with 11 and 19 SES were acquired in patients with THA. Semi-quantitative outcome measures were assessed on a five-point scale (1=best, 5=worst). The overall best image quality was determined. Statistical analyses included descriptive statistics, t-tests, multivariate regression models and partial Spearman correlations.

RESULTS

Scan times varied between 2:24 and 8:49 minutes. Reconstruction times varied between 3:14 and 85:00 minutes. Artifact reduction was optimal with an intermediate normalization factor (0.001) and improved with higher SES and iterations. Iterations >20 did not improve artifact reduction or image quality further. Ripple artifacts increased with higher SES and iterations. A normalization factor of 0.001 or 0.002 was best for reduction of blurring, while the soft tissue contrast was better and the distortion of soft tissue was less severe with lower normalization factors. Overall best soft tissue image quality was found for STIR and T1w images with 19 SES, 10 iterations and a normalization factor of 0.001 and for T2w images with 11 SES, 10 iterations and a normalization factor of 0.0005.

CONCLUSION

For the advanced acceleration and reconstruction algorithms of CS-SEMAC, optimal SES, iterations and normalization factors could

be identified. 19 SES and 20 iterations were sufficient for optimal artifact reduction, enabling an imaging protocol with clinically feasible acquisition and reconstruction times.

CLINICAL RELEVANCE/APPLICATION

Identified optimal CS-SEMAC MRI parameters may be applied in clinical practice and allow for improved evaluation of juxtaprosthetic tissue in patients with THA due to excellent artifact reduction.

PURPOSE

18F-Fluciclovine has shown promise in the detection and diagnosis of high-grade gliomas (HGG) due to minimal uptake in normal brain parenchyma and increased uptake in neoplastic tissue. The goal of this study is to evaluate 18F-fluciclovine PET uptake in patients with suspected recurrent HGG previously treated with chemotherapy and/or radiotherapy and correlate with overall survival.

METHOD AND MATERIALS

Nine patients with suspected recurrent HGG (WHO grade III, IV) previously treated with surgical resection followed by either chemotherapy and/or radiotherapy underwent dynamic 18F-fluciclovine brain PET. Average 18F-fluciclovine dose was 10.5 ± 0.41 mCi (390 ± 15 MBq). Semi-quantitative PET analysis (SUVmax, SUVmean) was performed for each lesion identified on standard of care MRI and compared to normal brain parenchyma and venous blood at all time points to obtain time activity curves. Metabolic tumor volume of each lesion was measured at each time point using a threshold of 1.6* normal brain parenchyma. True recurrence was confirmed with histopathological confirmation in 5 patients and subsequent serial MRI examinations.

RESULTS

18F-Fluciclovine uptake greater than background was visually identified in 6 of 9 patients. Average SUVmax and SUVmean of identifiable lesions were 5.7±1.2 and 1.4±0.5 at 60 minutes respectively. Average SUVmax and SUVmean for normal brain uptake were 1.8±0.6 and 0.5±0.2 respectively. Range of glioma SUVmax/normal SUVmean was 32.5 - 6.6 with an average ratio of 15.1±10.4. 18F-Fluciclovine PET identified a new distinct local metastasis in a patient that was confirmed on subsequent MRI examinations. Recurrent gliomas that were not visually identified by 18F-fluciclovine PET had an average SUVmax of 2.1±0.6 with a glioma SUVmax/normal SUVmean average of 6.1±1.7. The mean time of survival from the 18F-fluciclovine PET with identifiable recurrent HGG was 14.9 months vs 24.1 months for those lesions not visually identified on PET.

CONCLUSION

18F-fluciclovine PET/CT is a promising diagnostic tool for identifying recurrent HGG and may be a valuable tool for survival prognostication although more work is needed to verify these results.

CLINICAL RELEVANCE/APPLICATION

18F-fluciclovine PET/CT is a promising diagnostic tool for identifying recurrent HGG and may be a valuable tool for survival

prognostication.

SSE17-02 PET-MR Imaging Biomarkers Improving Differential Diagnosis Between Progression and Radionecrosis of Brain Tumors

nadya.pyatigorskaya@gmail.com

PURPOSE

Follow-up under treatment of patients with high grade glioma is essential, the MRI being the modality of choice. However, anatomical MRI may not be always reliable after radiation or chemotherapy. Advanced MRI techniques as well as PET were proposed for improving the diagnostic accuracy, that remains still moderate and variable across studies. Our purpose was to evaluate the diagnostic accuracy of PET-MRI for differential diagnosis between tumor progression and radionecrosis.

METHOD AND MATERIALS

Between December 2015 and September 2017, patients followed for primary malignant brain tumors underwent FDOPA PET-MRI. The acquisitions were performed with a 3T PET-MR system (SIGNA, GE Healthcare). The MRI acquisition included SE 3D T1-weighted images without and after contrast injection, 3D FLAIR imaging, DWI, pseudo-continuous arterial spin labeling (pCASL) and dynamic susceptibility-contrast (DSC) perfusion. The SUVmax, SUVmean, and SUVpeak were measured in each lesion with Volume of Interest (VOI). A region of interest was drawn in each lesion and the mean rADC, rCBV, and rCBF for both DSC and pCASL perfusion were calculated. In addition, the visual analysis was performed.

RESULTS

Forty-four patients were included. ROC analysis showed good discrimination between progression and radionecrosis with a good diagnostic accuracy for SUVmax (0.82), for SUVpeak (0.9) and for ASL rCBF (0.86). It was fair for rADC (0.63) and rCBV (0.75). A logistic regression model found among predictor variables, the combination of these SUVpeak and pCASL rCBF variables improved sensitivity (0.94), specificity (0.83), the AUC (0.97, 95% CI=[0.93,0.99]) and the accuracy (0.94). Visual analysis allowed a diagnostic accuracy of 0.77 for PET reading only, of 0.89 for PET reading with morphological MRI and of 0.98 for PET-MRI combined reading.

CONCLUSION

We have observed an increase in diagnostic accuracy for combined analysis of PET and MRI biomarkers for both qualititative and qualitative biomarkers, SUVpeak and pCASL rCBF being the most significant quantitative biomarkers. Combined PET-MR imaging allows to increase the diagnostic accuracy for differential diagnosis between tumor progression and radionecrosis in neuro-oncology.

CLINICAL RELEVANCE/APPLICATION

The combined analysis of imaging morphological, functional and metabolic markers on PET-MRI is helpful in differential diagnosis between tumor progression and radionecrosis in neuro-oncology.

SSE17-03 Detection of Abnormal Brain FDG-PET Images With Deep Learning

Monday, Nov. 26 3:20PM - 3:30PM Room: S505AB

Participants
Tomomi Nobashi, MD,PhD, Palo Alto, CA (*Abstract Co-Author*) Nothing to Disclose
Claudia Zacharias, MD, Seattle, WA (*Abstract Co-Author*) Nothing to Disclose
Andrei Iagaru, MD, Emerald Hills, CA (*Abstract Co-Author*) Research Grant, General Electric Company

Heying Duan, Stanford, CA (*Presenter*) Nothing to Disclose

PURPOSE

FDG-PET/CT is widely used in routine clinical practice and its utilization is projected to increase. The brain is often included as part of the study; however, due to its background physiological FDG uptake, the sensitivity for abnormality detection in this region is usually low. By utilizing a deep learning algorithm to aid radiologists detect abnormalities, clinical management and outcomes could be improved. The aim of this study was to evaluate the ability of a new deep learning framework to discern between normal and abnormal FDG uptake in the brain.

METHOD AND MATERIALS

285 FDG-PETs acquired between 2007 and 2017 were retrospectively reviewed. A deep learning framework was trained using 110 normal and 110 abnormal brain studies, including 10 studies for testing in each category. The remaining 36 normal and 29 abnormal studies were used for validation of the resulting inference model and its sensitivity and specificity were analyzed. DICOM studies were anonymized, appropriately windowed and converted into portable network graphics format. A network architecture that uses a time distributed 2D convolutional neural network with 100 epochs was generated. A classification was performed based on the probability of an individual FDG-PET scan being normal or abnormal. Various models were derived.

RESULTS

Accuracy and loss function of the optimal trained model were calculated at 0.761 and 0.462, respectively. Receiver operating characteristic (ROC) curve demonstrated an area under the curve of 0.832 (Figure 1). According to ROC curve, the optimal probability threshold to detect abnormal Brain FDG-PET scans was 0.661. Validation test characteristics resulted in sensitivity of 80.6% and specificity of 75.9%.

CONCLUSION

Preliminary results of a novel deep learning model showed promising capability in detecting brain abnormalities on FDG-PET images which could aid radiologists and improve clinical outcomes.

CLINICAL RELEVANCE/APPLICATION

Improving detection of brain FDG-PET abnormalities in daily clinical practice with the aid of a deep learning method that could help improve clinical management and outcomes.

PURPOSE

Posterior cortical atrophy (PCA) is a form of dementia considered to be an atypical variant of Alzheimer's disease (AD) and Dementia with Lewy bodies (DLB) is a type of posterior dementia characterized by fluctuating levels of cognition, changes in behavior, visual hallucinations with accompanying extrapyamidal motor symptoms. We attempt to identify specific core areas on FDG PET imaging which are common to both and also establish the differences which may be helpful to differentiating the two.

METHOD AND MATERIALS

We retrospectively analysed of 30 patients with clinically suspected posterior dementia. All the subjects underwent F-18 FDG PET CT scan of the brain and the studies were analyzed both qualitatively (visually) and semi-quantitatively. The subjects had undergone dopamine transporter imaging with Tc 99 m TRODAT 1 on a prior date. The subjects were divided into possible PCA with TRODAT scan normal (n=10) and possible DLB with abnormal (n=20). The FDG uptake patterns were recorded and areas of cortical hypometabolism in the cerebral cortex that were two standard deviations from the mean were considered as abnormal.

RESULTS

All the subjects had an abnormal pattern of F-18 FDG uptake on PET scan, both on visual inspection and semiquantitative analysis. Bilateral parieto-occipital hypometabolism was consistently found in all the subjects. Hypometabolism in precuneus, posterior cingulate and the cortex around the angular gyrus was present in all the subjects of PCA with relative sparing of the medial occipital cortices. DLB subjects showed variable degrees of involvement of the medial occipital cortices with relative sparing of posterior cingulate and precuneus.

CONCLUSION

FDG PET scan can act as a non-invasive diagnostic modality in differentiating the two posterior cortical dementias despite significant clinical and imaging overlap.

CLINICAL RELEVANCE/APPLICATION

We present features based on which FDG-PET can be used to diagnose and differentiate Posterior Cortical Atrophy (PCA) and Dementia with Lewy Bodies (DLB) in the clinical practice.

SSE17-05 Correlation of 4´-[methyl-11C]-thiothymidine Uptake with Human Nucleoside Transporter and Thymidine Kinase-1 Expressions in Patients with Newly Diagnosed Gliomas

PURPOSE

We examined expressions of four human nucleoside transporters including: human equilibrative nucleoside transporters (hENT1 and hENT2); and human concentrative nucleoside transporters (hCNT1 and hCNT3), and thymidine kinase-1 (TK1), the key enzyme in 4'-[methyl-11C]-thiothymidine (4DST) phosphorylation, to elucidate the mechanism of 4DST uptake in patients with newly diagnosed gliomas.

METHOD AND MATERIALS

A total of 19 patients with newly diagnosed gliomas were examined with 4DST PET. Tumor lesions were identified as areas of focally increased uptake, exceeding that of normal brain background. For semi-quantitative analysis, tumor-to-contralateral normal brain tissue (T/N) ratio was determined by dividing the maximal standardized uptake value (SUV) for tumor by that of the mean SUV for reference tissue. The expressions of hENT1, hENT2, hCNT1, hCNT3, and TK1 in tumor specimens were examined by immunohistochemistry and compared with 4DST T/N ratio.

RESULTS

All but two gliomas showed focally increased 4DST uptake. All but one grade II glioma that was not visualized with 4DST PET showed hENT1 staining. Of the gliomas, hENT2 and hCNT3 staining was observed in 11 and 16 gliomas, respectively. No hCNT1 staining was observed in any of the gliomas. All but two gliomas that were not visualized with 4DST PET showed TK1 staining. A significant correlation was observed between T/N ratio and hENT1 score ($r = 0.75$, $p < 0.001$). There was no significant correlation between T/N ratio and hENT2 score or hCNT3 score. There was a significant strong correlation between T/N ratio and TK1 score ($r = 0.92$, $p < 0.001$). It is likely that expression of TK1 might be more important than expression of hENT1 for uptake of 4DST.

CONCLUSION

Results of this preliminary study indicate that expressions of hENT1 and TK1 appear to be important determinants of 4DST uptake in newly diagnosed gliomas.

CLINICAL RELEVANCE/APPLICATION

Expressions of hENT1 and TK1 appear to be important determinants of 4DST uptake in newly diagnosed gliomas.

SSE17-06 A Novel Clustering Approach in Brain Tumors Using Dynamic 18F-FET PET/MRI

PURPOSE

Purpose of the present study is to present a user-independent, quantitative approach to easily classify brain areas on the base of uptake temporal evolution using dynamic 18F-FET PET/MRI.

METHOD AND MATERIALS

O-(2-18F-fluoroethyl)-L-tyrosine (18F-FET) PET/MRI performed at out Institution in brain tumors were retrospectively analyzed using a clustering technique in order to differentiate areas using uptake dynamics: time activity curves (TACs) were considered for each voxel in the brain volume and an unsupervised clustering algorithm was applied. This algorithm provides as output an automatic grouping of TACs and hence of voxels they are associated to. Therefore, it is possible to create parametric images, representing the different behavior over time of the tissues.

RESULTS

We were able to automatically identify brain areas grouped by dynamic similarities using 18F-FET uptake and produce parametric images (see Figure 1, panel (a)) and associated mean time-activity curves obtained averaging the TACs of voxels belonging to the same group (see Figure 1, panel (b)).

CONCLUSION

The proposed approach allows to exploit dynamic 18F-FET PET data: the automatic nature of the method removes the user-dependent ROI drawing step, the clustered data can be further analyzed to extract representative features of the average TACs and intuitive parametric images are produced. Moreover the method could be easily employed with other tracers.

CLINICAL RELEVANCE/APPLICATION

Validation of the method against pathological data is ongoing and seems to provide encouraging results. The method could then be used to plan areas for radiotherapy clustering areas with similar dynamic characteristics.

PURPOSE

To evaluate the effect of computer-aided diagnosis (CAD) on different level radiologists' performance for discriminating malignant from benign thyroid nodules on US images.

METHOD AND MATERIALS

From January 2013 to December 2017, thyroid nodules with decisive diagnosis on the basis of pathologic results were consecutively enrolled. The observer study was conducted with four experienced radiologists and four radiology fellows, all of whom analyzed the thyroid nodules using 2017 ACR TIRADS first without and subsequently with CAD software. The performance of each observer without and with the CAD was assessed by measuring the area under the receiver operating characteristics curve (Az), sensitivity, specificity, PPV and NPV. To quantify the changes in clinical management decisions with the CAD aid, we computed for each radiologist the number of malignant and benign nodules for which the clinical management decision was changed. Concordance between observers in classing the thyroid nodules was measured in without and with CAD conditions.

RESULTS

In total, 1065 thyroid nodules from 1035 patients were included; 382 (35.87%) were benign and 683 (64.13%) were malignant. Use of the CAD resulted in an improvement of the average performance of the 8 observers, as measured by means of a statistically significant increase in Az value (0.840-0.853; $p < .000$) , sensitivity (86.44%-87.52%; $p < .000$) and inter-observer agreements(0.744-0.769; $p < .05$) A statistically significant difference was not found in the specificity without and with the computer aid (38.74%-38.55%; $p = .20$). On the basis of TI-RADS assessments, it was estimated that with CAD, each observer, on average, correctly recommended 1.02% (7/683) of additional biopsies and also increased 0.37% (1.4/382) of unnecessary biopsies.

CONCLUSION

Computer-aided diagnosis can help radiologists improve their sensitivity in detection of thyroid malignancies and also increased the rate of unnecessary biopsies.

CLINICAL RELEVANCE/APPLICATION

To aid diagnosis for inexperienced radiologists and decrease workload

SSE18-02 Comparision of Morphology and Enhancement Characteristics of Ectopic and Eutopic Parathyroid Adenomas.

PURPOSE

4D-CT is a novel technique for pre-surgical localization of parathyroid adenomas (PA). PA can be eutopic or ectopic. Detection of ectopic PA is crucial for surgical success especially if patient has multigland disease with both eutopic and ectopic PA. Purpose of our study is to determine the differences in morphology and enhancement characteristics between eutopic and ectopicPA which will help in increasing the confidence of radiologist for suggesting high probability.

METHOD AND MATERIALS

This is an IRB approved retrospective study of 232 patients with surgically proven PA who underwent 4D CT imaging for pre surgical localization of PA between 2014 and 2017. All 4D CT scans were performed with initial noncontrast followed by 30 sec and 90 sec postcontrast images on 64 slice MDCT scanner. Contrast washout ratios (CWR) were calculated by measuring Hounsfield units (HU) of PA on the noncontrast, 30 second post contrast early arterial exam (30A) and on the 90 second post contrast delayed exam (90D). CWR = [100 x (HU on 30A - HU on 90D)/HU on 30A].

RESULTS

Out of 232 patients, 186 patients - 1 gland, 37 patients - 2 gland, 6 patients - 3 gland and 3 patients- 4 gland adenomas constituting a total of 290 radiologically diagnosed lesions. Out of these, 25 (6M, 17F) PA were in ectopic and 265 (37M, 228F) PA were eutopic. Out of 290 radiologically reported lesions, 242 lesions (21 Ectopic and 221 Eutopic) matched to the adenomas found on surgery and pathology constituting to 242 radiological-surgical-pathology matched lesions. 48 lesions were false positive, which did not correlate with the location on surgical pathology. Morphological characteristics like shape, size, heterogeneity were studied and compared between eutopic and ectopic adenomas. Enhancement characteristics of eutopic and ectopic adenomas were compared and were categorized at 10% washout intervals, for example: 1-10%, 11-20% and so on.

CONCLUSION

1. 217 out of 265 eutopic adenomas and 20 out of 25 ectopic adenomas demonstrated contrast washout ratios between 31%-80% and did not demonstrate significant difference in washout characteristics. 2. Size and shape of ectopic PA did not show significant influence on washout characteristics. 3. Measurement of contrast enhancement and washout dynamics is limited in lesions with large cystic areas.

CLINICAL RELEVANCE/APPLICATION

Detection of ectopic PA is crucial for surgical success especially in the setting of multigland disease.

SSE18-03 The Assessment of Cervical Lymph Node Metastasis from Thyroid Cancers: A Quantitative Analysis on Multiphasic CT

PURPOSE

Purpose: The purpose of this study was to evaluate the diagnostic performance of multiphasic CT in the discrimination of metastatic lymph nodes of papillary (PTC) and medullary (MTC) thyroid cancers from non-metastatic ones with the use of quantitative parameters.

METHOD AND MATERIALS

Materials-methods: This study enrolled 62 pathologically proven metastatic and 62 benign lymph nodes from 23 thyroid cancer patients (19 PTC and 4 MTC). Multiphasic CT was utilized by using non-enhanced, arterial (25-second delay) and venous (80-second delay) phases. Two readers independently measured mean tissue attenuation values (MAV) of metastatic and benign lymph nodes. The relative wash in and wash out percentages were calculated and were defined as: arterial MAV-nonenhanced MAV/nonenhanced MAV, venous MAV- arterial MAV/arterial MAVx100; respectively.

RESULTS

Results: The difference in MAV between metastatic and benign lymph nodes for the PTC were maximum in the arterial phase ($p<0.001$). The arterial phase showed the highest diagnostic performance compared with other phases for the PTC (AUC±SE:0.98±0.01; %95 CI: 0.96-1). A cutoff value of 97.5 HU for the arterial phase had a sensitivity of 96.3% (%95 CI: 87.5-99%) and specificity of 94.4% (%95 CI: 84.8-98.1%), positive predictive value (PPV) of 97.2% and negative predictive value (NPV) of 92.6% in the discrimination of metastatic lymph nodes from PTC ($p<0.001$). Metastatic lymph nodes from MTC showed progressive enhancement compared to benign lymph nodes and the venous phase showed the highest diagnostic performance in discrimination between metastatic and benign lymph nodes ($p<0.05$). A MAV cutoff of 112.5 HU in the venous phase predicted metastatic lymph nodes from MTC with a sensitivity of 87.5%, specificity of 75%, ($p=0.015$).

CONCLUSION

The detection of metastatic lymph nodes from thyroid cancers can be achievable with the use of quantitative parameters in

multiphasic CT. Metastatic lymph nodes from PTC show strong uptake of contrast in the arterial phase and wash out of contrast in the venous phase. Whereas, metastatic lymph nodes from MTC show progressive enhancement in the venous phase.

CLINICAL RELEVANCE/APPLICATION

Determination of metastatic lymph nodes is an important problem in thyroid cancers. Complete resection of the primary disease and metastases is the one of the important factor in the survival.

SSE18-04 Retrospective Analysis of Thyroid Ultrasound Recommendations Using Thyroid Imaging Reporting and Data System (TI-RADS) Scoring

Monday, Nov. 26 3:30PM - 3:40PM Room: E351

Awards
Student Travel Stipend Award

Participants
Charles E. Runyan III, MD , Phoenix, AZ (*Presenter*) Nothing to Disclose
Alexia Tatem, BS, Cave Creek, AZ (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Breast Imaging, Reporting, and Data System (BI-RADS) has been used to standardize mammogram reports and recommendations; Thyroid Imaging, Reporting, and Data System (TI-RADS) seeks to do the same. We compared our institution's prior biopsy recommendations on ultrasound reports to what the recommendations would have been using TI-RADS.

METHOD AND MATERIALS

Our study was a retrospective review of 449 thyroid nodules which were assessed by ultrasound and subsequently biopsied. We collected the description of the lesion and the original recommendations from the radiology report. Pathology results were collected. Three radiologists then performed blinded and independent evaluations of each exam; a TI-RADS score was assigned to each thyroid nodule. Recommendations based on TI-RADS were compared with prior recommendations and biopsy results.

RESULTS

449 thyroid nodules were identified by review of biopsies. Had we implemented TI-RADS, we would have recommended 102 fewer biopsies (23%). No nodules for which a biopsy was initially recommended but not recommended by TI-RADS criteria demonstrated a clinically significant malignancy at biopsy. Incidental foci of papillary carcinoma found within benign follicular nodules less than 0.5cm were considered not clinically relevant, as studies have shown that 5-30% of autopsies have found occult papillary carcinoma in patients who died of unrelated causes. Our positive predictive value before implementing TI-RADS was 8.2%. Utilizing TI-RADS, our positive predictive value is 10.5%, a ~25% difference.

CONCLUSION

There was a decrease in the number of thyroid biopsies that would have been recommended when using TI-RADS. We demonstrated a 23% decrease in the number of recommended biopsies without decreasing our ability to identify clinically significant malignancies. Findings suggest that implementing TI-RADS will decrease the number of negative biopsies performed, which will decrease patient risk and worry as well as save the health system from the cost of these additional procedures. Our study is limited by only selecting patients who underwent biopsy. Due to our inclusion criteria, we did not assess for any missed malignancies in nodules presumed to be benign on prior ultrasound reports.

CLINICAL RELEVANCE/APPLICATION

Use of TI-RADS for thyroid nodule biopsy recommendations can greatly reduce the number of biopsies recommended without missing a clinically significant malignancy.

SSE18-05 Machine Learning Optimization of 4D-CT and 99m-Technetium Sestamibi for Preoperative Localization in Patients with Primary Hyperparathyroidism

PURPOSE

The purpose of this study is to apply machine learning to 4D-CT and 99mTechnetium sestamibi (MIBI) for preoperative localization of hyperfunctioning parathyroid glands in patients with primary hyperparathyroidism (PHPT). Our aim is to develop a model and decision tree algorithm to maximize diagnostic accuracy.

METHOD AND MATERIALS

A retrospective study of 400 patients who underwent combined imaging protocol of 4D-CT and MIBI SPECT/CT and subsequent parathyroidectomy was performed. Four parathyroid glands were assumed for each patient (n=1600). Reference standard was surgical pathology. Both 4D-CT and MIBI were interpreted by two nuclear radiologists. Using machine learning, a random-forest tree

algorithm using 3-fold cross validation was trained and validated to predict the probability of a parathyroid gland as positive hyperfunctioning gland on pathology (adenoma or hyperplasia). A total of 17 variables were used, including 4 clinical, 10 biological, and 3 imaging variables. Imaging variables included 4D-CT, MIBI, and combined 4D-CT+MIBI.

RESULTS

Of 1600 parathyroid glands, 521 were abnormal on surgical pathology. The model output was probability of a gland as positive on pathology. The final model selected variables of combined 4D-CT+MIBI and preoperative serum PTH and Calcium crossproduct (PTH*Ca). The AUC of the model was 0.99 (95 CI: .984-.996) and outperformed AUC of radiologist interpretation of 4D-CT and MIBI, alone and in combination. When both 4D-CT and MIBI are positive, the probability of a true positive is 97% (n=305) and when either test is positive, the probability is 75% (n=164). When both tests are negative, the gland is a true negative in 96% of cases if PTH*Ca is > 1232 (n=333), 92% of cases if PTH*Ca>675 and <1232 (n=563) and 81% of cases if PTH*Ca<675 (n=297).

CONCLUSION

Diagnostic accuracy of preoperative 4D-CT and MIBI is improved with machine learning compared with radiologist interpretation. A decision tree algorithm simplified into three variables selected by machine learning can provide probability of correct classification of each parathyroid gland as normal or abnormal and guide the surgeon to pursue minimally invasive parathyroidectomy or 4-gland exploration.

CLINICAL RELEVANCE/APPLICATION

Machine learning-derived model and decision tree algorithm can improve diagnostic accuracy of preoperative localization of 4D-CT and 99mTechnetium Sestamibi for patients with primary hyperparathyroidism.

SSE18-06 Utility of Ultrasound Elastography (Acoustic Radiation Force Impulse Imaging) in the Diagnosis of Parathyroid Adenoma in Correlation with Sestamibi Scan

PURPOSE

In this study we consider applying the technique of ARFI with Virtual Touch Quantification (a type of quantitative elastography) in diagnosis of parathyroid adenomas(most common cause of primary hyperparathyroidism), to prospectively assess whether this technique can increase the diagnostic value of ultrasound approaching nearer to or more than the sensitivity and specificity of sestamibi scan.

METHOD AND MATERIALS

This was a prospective observational study conducted in the department of radiodiagnosis of our institution from October 2016 to December 2017. The study population consisted of 36 patients(n=36) with clinical suspicion of primary hyperparathyroidism with positive Sestamibi scan for parathyroid adenoma irrespective of ultrasound results(done prior to the Sestamibi scan). The parathyroid adenoma was first identified by grey scale imaging features and then a region of interest for elastography was placed within the lesion and the stiffness of the lesion using ARFI-VTQ values were obtained. Five successful measurements were taken for ARFI -VTQ(measured in meters per second) and the median value was calculated.

RESULTS

Ultrasound elastography was performed on all the 36 cases of adenomas and the median ARFI-VTQ values were calculated. The mean ARFI values of the corresponding adjacent thyroid tissue were also calculated.The mean ARFI-VTQ values of adenomas was (1.72±0.45m/s).The mean ARFI-VTQ values of normal thyroid tissue was (2.66±0.38m/s).There was a statistically significant difference between the two variables with [p <0.0001]. The study shows a consistently low elastography values for adenomas than adjacent thyroid tissue and other lesions which mimic adenomas like lymph nodes . Thus ultrasound along with ARFI-VTQ values has high accuracy in diagnosing adenomas.

CONCLUSION

Ultrasound elastography(withARFI-VTQ)is an excellent tool which enhances the diagnostic value of ultrasound in parathyroid adenomas when used along with B-mode ultrasound and doppler.

CLINICAL RELEVANCE/APPLICATION

In clinically diagnosed patients of hyperparathyroidism ultrasound ARFI-VTQ can be applied as a solitary imaging modality(in place of sestamibi), since it is an excellent diagnostic imaging tool in the diagnosis of normally located parathyroid adenomas with high accuracy.

PURPOSE

Asymmetry of hippocampal internal architecture (HIA) clarity has been regarded as a sign of hippocampal sclerosis (HS). The aim of this work was to compare HIA in patients with medial temporal lobe epilepsy (MTLE) in 3T and 7T MRI in lateralizing epileptic side and its relationship with postoperative seizure outcome

METHOD AND MATERIALS

39 patients with MTLE were recruited, and MRI at 3 T and 7T were obtained respectively (GE Discovery MR750 3T and Siemens Investigational Device 7T) for semi-quantitative assessment of the HIA by visual scoring system (Ver Hoef et al., 2013). The values of the average HIA scores of 3T and 7T MRI in the epileptogenic and non-epileptogenic hippocampi were compared with Kruskal-Wallis H test. Pair-wise differences between groups were evaluated with Mann-Whitney U test. A logistic regression model examined the utility of average HIA asymmetry score in lateralizing seizure onset determined by video-EEG. 25 patients underwent amygdalohippocampectomy and received postoperative follow up. The relationship between HIA and postoperative seizure freedom was investigated

RESULTS

HIA scores of the epileptogenic hippocampi were lower than that of non-epileptogenic hippocampi either in 3TMRI (P=0.0166) or 7TMRI (P=0.0014). The HIA scores of either side of hippocampi in 7T MRI were higher than that of 3T MRI (Contralateral P < 0,0001, Ipsilateral P=0.0002). Logistic regression analysis showed that the HIA asymmetry score either in 3T MRI or 7T MRI was the strong predictor of epileptic laterality (3T MRI: B = 1.504, P = 0.033; 7T MRI: B = 1.705, P = 0.019). However, there were no significant differences in HIA asymmetry score between patients rendered seizure free (ILAE 1) compared to those continuing to experience seizures (ILAE 2-5) either in 3T MRI or 7T MRI.

CONCLUSION

7T MRI was relatively superior to 3TMRI in displaying the subtle hippocampal internal architecture for its higher HIA scores. HIA asymmetry is a significant predictor in lateralizing epileptic side of MTLE patients either in 3T MRI or 7T MRI, but not in the surgical outcomes of the patients

CLINICAL RELEVANCE/APPLICATION

The superiority of 7T MRI in presenting subtle hippocampal internal architecture may help lateralize epileptic side of temporal lobe epilepsy on early side or without evident hippocampal sclerosis in 3T MRI

PURPOSE

Mesial temporal sclerosis (MTS) is a common cause of surgically treatable epilepsy in adults. MTS is frequently, but not always, detectable on MRI. The purpose of this project was to determine if deep learning using a convolutional neural network can be used to detect MTS on MRI.

METHOD AND MATERIALS

Anonymized volumetric T1 weighted MRIs were retrospectively obtained from 88 normal controls and 119 patients with a clinical and EEG consensus diagnosis of MTS. Of the MTS patients, 39 were read as no MTS on MRI and 80 were read as having MTS during routine clinical interpretation. These studies were divided into training(173), validation (17) and test(17) groups each with a similar distribution of MRI types. The images were bias corrected and the hippocampi were segmented using FSL(Analysis Group, FMRIB, Oxford, UK). The hippocamal segmentations were used to construct bounding boxes around each hippocampus which was utilized during model training. Using TensorFlow, a 3D convolutional neural network modeled after the VGG architecture was constructed and trained to predict normal vs MTS and to locate a bounding box around each hippocampus.

RESULTS

During training, the maximum accuracy achieved on the validation set was 100%. Using the model weights from that epoch, an accuracy of 88% was achieved on the test set with a sensitivity of 89% and a specificity of 88%. For comparison, the sensitivity of the human interpretation for detection of MTS in this cohort of patients with clinical and EEG consensus diagnosis of MTS was 67%.

CONCLUSION

On this small sample, deep learning methods show potential utility for automating the detection of MTS on MRI, warranting further investigation.

CLINICAL RELEVANCE/APPLICATION

Deep learning has the potential to aid in detecting MTS in epilepsy patients

SSE19-03 In Vivo Measurements of GABA and Glutamate-Glutamine in Nocturnal Frontal Lobe Epilepsy

Monday, Nov. 26 3:20PM - 3:30PM Room: E352

Participants
Weina Wang, Chengdu, China (*Presenter*) Nothing to Disclose
Xiaorui Su, Chengdu, China (*Abstract Co-Author*) Nothing to Disclose
Huaiqiang Sun, Chengdu, China (*Abstract Co-Author*) Nothing to Disclose
Simin Zhang, Chendu, China (*Abstract Co-Author*) Nothing to Disclose
Qiyong Gong, MD, PhD, Chengdu, China (*Abstract Co-Author*) Nothing to Disclose
Qiang Yue, Chengdu, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Nocturnal frontal lobe epilepsy (NFLE) is a focal epilepsy with seizures arising mainly during sleep and characterized by violent limb movement or tonic-dystonic postures. The major inhibitory and excitatory neurotransmitters, γ-aminobutyric acid (GABA) and glutamate, respectively, are implicated in the pathophysiology of NFLE. This study aimed to compare the measurements of GABA, and glutamate-glutamine (Glx) levels in NFLE subjects.

METHOD AND MATERIALS

Study participants were recruited at the seizure disorders outpatient clinic from November 2013 to July 2017. T1-weighted images were acquired and reconstructed for the spectral voxels using a 3T system. Proton magnetic resonance spectroscopy was used to measure GABA and Glx levels in the bilateral dorsolateral prefrontal cortex (DLPFC) regions with a voxel size of 4.0 × 2.0 × 1.5 cm3. Figure 1 illustrates voxels position. Spectra were analyzed using 'Gannet'. The GABA and Glx levels were expressed in 'institutional units' as ratios of peak areas relative to the Cr signal. Only spectra with a relative fitting error generated by GannetFit below 15%, and FWHM below11 Hz were included.

RESULTS

Demographic information is provided in table 1. Thirty-nine subjects with NFLE and 63 controls participated in this study with well-matched for age and gender. As shown in Figure 2, Glx level in the right DLPFC region was higher in NFLE compared with controls (P=0.020). We did not find any GABA level alterations in the current study. In NFLE patients there was significant positive correlations between illness duration and right DLPFC glx level (R2=0.514, P=0.05).

CONCLUSION

In patients with seizures characterized by complex motor behaviors, the region of seizure onset may involve the DLPFC. In line with our finding, elevations in Glx were also observed in idiopathic generalized epilepsy, which may imply increased neuronal excitability. A significant positive correlation was found in NFLE subjects between Glx levels and illness duration, indicating that the longer illness duration may due to severer hyperactivity. These findings are interpreted in terms of a pathophysiological model of NFLE in which excitatory neurotransmission abundance in right DLPFC could lead to hyperexcitability and, potentially seizures-related neuronal dysfunction.

CLINICAL RELEVANCE/APPLICATION

(dealing with MRS) 'MRS exam in possible focus region is recommended in epilepsy patients.'

SSE19-04 White Matter Regional Based Analysis Using Diffusion Tensor Tractography in Patients with Temporal Lobe Epilepsy and Correlation with Patient Outcomes

Monday, Nov. 26 3:30PM - 3:40PM Room: E352

Participants
Mahdi Alizadeh, Philadelphia, PA (*Presenter*) Nothing to Disclose
Lauren Kozlowski, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose
Jennifer Muller, MS,BS, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose
Feroze B. Mohamed, PhD, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose

Chengyuan Wu, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

In this study, we aim to evaluate the use of diffusion tensor tractography (DTT) as a predictive model of temporal lobe epilepsy (TLE) and correlate their clinical significance with respect to postsurgical outcome. Automated regional based white matter analysis was used to compare the tract density in two groups of TLE patients: responders and non-responders to the surgical treatments.

METHOD AND MATERIALS

A total of 19 patients with TLE underwent either a craniotomy anterior temporal lobectomy (ATL) or a Selective Laser Amygdalohippocampectomy (SLAH) and were imaged using 3.0T Philips Achieva MR scanner. DTI images were acquired axially in the same anatomical location prescribed for the T1-weighted images. The raw data set of the diffusion volumes were first corrected for eddy current distortions and motion artifacts. Track density imaging (TDI) of 68 white matter parcels were generated using fiber orientation distribution (FOD) based deterministic fiber tracking and compared between responders (10) and non-responders (n=9) to the surgical treatments.

RESULTS

looking at tract density of white matter parcels, significant increases have been observed in five distinct white matter parcels (Table 1) in non-responders. These regions are included ipsilateral lingual (p=0.04), ipsilateral temporal pole (p=0.007), ipsilateral pars opercularis (p=0.03), ipsilateral inferior parietal (p=0.04) and contralateral frontal pole (p=0.04).

CONCLUSION

The significant decreases exhibited in tractography on the ipsilateral hemisphere as the pathological process are likely attributed to direct effects of the sclerotic disease such as the ipsilateral temporal pole in TLE patients [9]. These findings may also be attributed to extensions of the disease process/disruptions in connections to adjacent structures, for instance, the ipsilateral lingual gyrus which joins the parahippocampal gyrus and is a continuation of the tentorial surface of the temporal lobe.

CLINICAL RELEVANCE/APPLICATION

These results may have the potential to be developed into imaging prognostic markers of postoperative outcomes and provide new insights for why some patients with TLE continue to experience postoperative seizures if pathological/clinical correlates are further confirmed. On the contrary, arears predicting unfavorable postsurgical outcome were distinct, suggesting different configuration of epileptogenic networks between responders and non-responders.

SSE19-05 Assessment of ASL Perfusion MRI as an Imaging Biomarker in Seizure: Imaging Timing and Perfusion Pattern Analysis

Monday, Nov. 26 3:40PM - 3:50PM Room: E352

Participants
Jungbin Lee, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose
Aleum Lee, MD, Bucheon-Si, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

noiese@icloud.com

PURPOSE

The aim of the study is to identify time-related perfusion change after seizure by ASL-PWI, and to evaluate additional values of ASL-PWI in seizure patients.

METHOD AND MATERIALS

The ASL-PWI and EEG were performed on 61 patients who suspected seizures. The electronic medical records of the patients were reviewed to record the time intervals between seizure and MR imaging, seizure semiology, multiplexity and suspected seizure etiology. And we analyzed perfusion abnormality on ASL-PWI in each patient by pattern of perfusion maps (increase/decrease) and location of the abnormality. Then the concordance of location which showed abnormality between ASL-PWI and EEG was scored from 0 to 4 and compared ASL-PWI findings with conventional MRI findings.

RESULTS

The time interval between seizure attack and ASL-PWI ranged from 0.5 ~ 121.5 hrs (mean period, 31.6 hr). 5 patients (8.2%) were performed MR imaging shorter than 6 hours, 9 (14.8%) were 6-12 hours, 27 (29.5%) were 6-24 hours and 29 (47.5%) were longer than 24 hours. There was a negative linear correlation between time interval and concordance of location with statistically significant (p=0.040). In single seizure group, the first hypoperfusion was 13 hours and the last hyperperfusion was 26 hours. Delayed hyperperfusion (>24hrs) seems to be related with multiple seizures. In normal routine MRI group, 56.8% (21/37) showed abnormal ASL-PWI results. In abnormal routine MRI group, 29.1% (7/24) showed perilesional perfusion change.

CONCLUSION

ASL-PWI findings after seizure, although are time-dependent and challenging to analysis, but since abnormal perfusion findings on ASL-PWI is observed in many seizure patients and have added values, ASL-PWI is recommended in a routine seizure protocol

CLINICAL RELEVANCE/APPLICATION

By adding ASL-PWI in seizure protocol, the accuracy of the seizure diagnosis can be improved and the estimation of epileptogenic foci can be assisted.

SSE19-06 Interhemispheric White Matter Asymmetries Are Distinctly Affected in Left and Right Medial Temporal Lobe Epilepsy with Hippocampal Sclerosis

Monday, Nov. 26 3:50PM - 4:00PM Room: E352

Participants
Xu Zhao, Wuhan, China (*Presenter*) Nothing to Disclose

zhaoxu96@163.com

PURPOSE

Many past studies reported the asymmetrical structural and/or functional changes of mesial temporal lobe epilepsy (MTLE), that is, the abnormalities in the ipsilateral were more obvious than the contralateral hemisphere in both left MTLE (LMTLE) and right MTLE (RMTLE).However, none of these studies compared the left hemisphere to right hemisphere directly and the asymmetry traits of MTLE remain largely unconfirmed. Thus, this study aims to investigate the white matter microstructure asymmetries of MTLE by compare the two hemispheres directly.

METHOD AND MATERIALS

25 MTLE patients with unilateral hippocampal sclerosis (HS) (LMTLE-HS group, n=13; RMTLE-HS group, n=12) and 26 health controls (HC) were enrolled. Diffusion tensor imaging (DTI) data were analyzed by tract-based spatial statistics (TBSS) to test the hemispheric differences across the entire white matter skeleton. We also conducted two-sample paired t-test for 21 paired-ROIs parceled on the basis of ICBM-DTI-81 white-matter labels atlas of bilateral hemispheres. An asymmetry index (AI) was calculated using the formula AI=100*[Right-Left]/[(Right+Left)/2] to further quantify the differences between the left and right paired-ROIs mentioned above.

RESULTS

The asymmetries across a large number of white matter skeletons were significantly reduced in LMTLE-HS group and RMTLE-HS group compared to HC. ROI-based quantitative analysis of FA/MD showed the asymmetry traits of fornix (FORX), cingulum (hippocampus), cingulum (cingulus gyrus), uncinate fasciculus (UF),superior longitudinal fasciculus (SLF) and superior fronto-occipital fasciculus (SFOF) were disappeared in LMTLE-HS and/or RMTLE-HS group. Apart from that, the intergroup analysis of AI revealed no significant difference between LMTLE-HS group and HC, but some differences were showed when compared RMTLE-HS with LMTLE-HS or RMTLE-HS with HC.

CONCLUSION

The asymmetry traits of MTLE patients were reduced compared to HC. The AI between LMTLE-HS and HS did not show any significant difference indicated that LMTLE-HS might impair the two hemispheres equally. The differences of AI between RMTLE-HS and LMTLE-HS indicated that they might have different mechanisms.

CLINICAL RELEVANCE/APPLICATION

The different asymmetry traits among LMTLE-HS, RMTLE-HS and HC may be able to differentiate LMTLE-HS from RMTLE-HS and thus may be useful for locating side of seizure lesions in MTLE patients.

PURPOSE

Direct data from human subjects on the validity of the "critical period" of brain development and the permanent detrimental impact of sensory deprivation during this period is lacking. We present evidence for neural plasticity in congenitally blind children following sight restoration.

METHOD AND MATERIALS

Pre- and post-treatment scans of 15 participants (8 to 24 years) who had been treated for bilateral congenital blindness were done on a 3.0T MRI (750w, GE Healthcare) using a 32 channel brain coil. A high-resolution T1-weighted fast spoiled gradient echo anatomical scan was acquired for each participant. To measure blood oxygen level dependent (BOLD) contrast, 35 slices parallel to the AC/PC were acquired using standard T2 weighted gradient-echo echoplanar imaging. A diffusion-weighted scan (40 direction + 5 b0; 74.4 ms TE; 13.7s TR; 2x0.86x0.86 mm3; FOV: 256 x 256 x 72; b = 1000 nm/s2) was performed for diffusion tensor tractography.

RESULTS

Using functional connectivity analyses, we find marked changes in the functional organization of the visual cortex. There is a significant enhancement of cortical decorrelation as a function of time following sight onset. The fusiform facial area (FFA) and occipital facial area (OFA) develop rapidly. Structural imaging demonstrates increase in both volume and thickness of grey matter compared to controls, especially in the fusiform. Analysis of the optic tract in the same participants revealed no change in mean diffusivity (MD) and fractional anisotropy (FA) during the post-treatment period, while the FA of the optic radiation decreased steeply over 2 years.

CONCLUSION

Contrary to our expectation of limited neural plasticity late in the developmental timeline, we find strong evidence of brain malleability using both functional and structural imaging. Our findings help explain the behaviourally observed gains in visual proficiency congenitally blind individuals exhibit as a function of time after sight restoring surgery.

CLINICAL RELEVANCE/APPLICATION

Our study presents evidence for brain plasticity and hence opens up treatment avenues for conditions such as late-diagnosed congenital blindness.

SSE20-02 Evolution of Brain Dynamics in the First 2 Years of Life

Monday, Nov. 26 3:10PM - 3:20PM Room: E350

Participants
Xuyun Wen, Chapel Hill, NC (*Presenter*) Nothing to Disclose

Dinggang Shen, Chapel Hill, NC (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Brain is a dynamic system with its state varying all the time. Increasing evidences have indicated that the brain dynamics may evolve in early development and contribute to the cognitive development. This study uses resting-state fMRI and dynamic graph analysis to delineate how such dynamics develop in the first 2 years of life.

METHOD AND MATERIALS

Seventy-two normal infants at 0-, 1- and 2-years old were recruited. After data preprocessing, we extracted regional mean BOLD time series (140 TRs) from 116 pre-defined regions based on AAL atlas and constructed a temporal adjacency network by treating each TR as a node and the similarity (measured by inverse Euclidean distance) in brain states between two different TRs as an edge. Here, each brain state is a momentary (single TR) pattern of the BOLD activities at the 116 brain regions. We performed a subject-level clustering on the temporal adjacency network to divide the brain states into several groups. For each group, we generated a representative state by averaging all time series with the same state. To identify the common states in age groups, we used a second-level clustering over the subject-level state network, where nodes are identified as brain states of the subjects and edges are the similarity between pairs of brain states.

RESULTS

We observed three major brain states that frequently occurred across almost all ages (see histograms in Fig.1). We found these three states could be one-to-one matched across age groups. The first state displays high activities in the sensorimotor cortex, while the second state shows high activities in the visual cortex. In the third state, high activities in the higher-order cognition-related areas are prominent. The first state is highly consistent across all age groups. The second state has a higher similarity between 0- and 1-year-old. For the third state, the later two age groups are much more similar.

CONCLUSION

In closing, three common brain states were identified from 0- to 2-years-old, but showing different similarities across age groups. Such state-level differences may be due to the brain evolution in the first 2 years of life to support the development of the cognitive function.

CLINICAL RELEVANCE/APPLICATION

This study is helpful to better understand the infancy normal neurodevelopment and provides a baseline for the disease diagnosis in early ages.

SSE20-03 Evaluating Normal Fetal Brain Development in 25-39 Weeks Gestational Age Using IVIM-DWI: A Preliminary Study

PURPOSE

To evaluate the age-related normal changes of water diffusivity and perfusion in the fetal brain using intravoxel incoherent motion diffusion weighted imaging (IVIM-DWI).

METHOD AND MATERIALS

This study was approved by the local Ethics Committee and informed consents were obtained. Seventy nine normal singleton fetuses between 25-39 weeks of gestation were scanned without sedation of healthy pregnant women. The multi-b DWI with 9 b-values (0 - 800 sec/mm2) was performed using a 1.5-Tesla MR scanner. Pure diffusion coefficient (D), pseudo-diffusion coefficient (D*) and perfusion fraction (f) values were measured in white matter (frontal, parietal, temporal and occipital lobe), cerebral hemisphere (CH), thalamus (TH), basal ganglia region (BGR) and pons using an IVIM model. D, D* and f values were compared among different brain regions with one-way ANOVA. Correlation between IVIM parameters and gestational age (GA) was assessed with quadratic polynomial regression.

RESULTS

Statistical difference in D and f values were found among the different right brain regions (D values, $F = 96.644$, $P < 0.0001$; f values, $F = 105.598$, $P < 0.0001$). Mean D values in supratentorial deep white matter areas were higher than those in other regions ($P < 0.0001$). There were significant negative correlation between GA and D values in CH, BGR, TH and pons (CH, $R2 = 0.49$, $p < 0.0001$; BGR, $R2 = 0.33$, $P < 0.0001$; TH, $R2 = 0.12$, $p = 0.0014$; pons, $R2 = 0.22$, $p < 0.0001$). D values in supratentorial regions gradually increased before 29th GA and then decreased. The f values in the pons were positively related with GA ($R 2 = 0.23$, $p = 0.0325$). The f value was higher at 32-36 GA in other brain regions.

CONCLUSION

These results suggested that IVIM-DWI parameters is promising in evaluating the fetal brain development.

CLINICAL RELEVANCE/APPLICATION

no

PURPOSE

Studies suggest that quantitative susceptibility mapping (QSM) may be sensitive to brain changes related to Alzheimer's disease (AD) and vascular dementia. However, these studies are typically performed with clinical diagnosis, and are susceptible to contributions from unidentified pathology. In contrast, measuring the underlying neuropathology through histology allows for an accurate assessment of neuropathologic burden. Therefore, this work investigated the associations of magnetic susceptibility with multiple age-related neuropathologies by combining ex-vivo QSM and histology in a large community cohort of older adults.

METHOD AND MATERIALS

Postmortem cerebral hemispheres were obtained from 223 participants of two longitudinal cohort studies of aging. Each hemisphere was imaged on a 3T MR scanner with 3D gradient-echo and 2D spin-echo sequences. Ex-vivo magnetic susceptibility maps were generated using the MEDI toolbox and spatially transferred to a template constructed by applying the "unbiased atlas construction via group-wise DRAMMS registration" tool to the spin-echo data. A board-certified neuropathologist, who was blinded to age and clinical diagnoses, evaluated each hemisphere for neurodegenerative and vascular pathologies: AD, Lewy bodies, hippocampal sclerosis (HS), TDP-43, arteriolosclerosis, atherosclerosis, cerebral amyloid angiopathy, gross and microscopic infarcts. Voxelwise linear regression of the participants' magnetic susceptibility values was conducted with the neuropathologies and demographics as independent variables. Statistical significance was achieved at $p<0.05$ for the FDR-adjusted p-values.

RESULTS

Significant associations were discovered between magnetic susceptibility and measures of AD, HS, arteriolosclerosis, gross and microscopic infarcts.

CONCLUSION

This work demonstrated that magnetic susceptibility shifts linked to age-related neuropathologies can be detected by QSM. Both neurodegenerative and vascular pathologies were linked to magnetic susceptibility. These findings are expected to translate well to in-vivo QSM, as it was recently shown that ex-vivo magnetic susceptibility can be linked to in-vivo magnetic susceptibility for this work's experimental setup.

CLINICAL RELEVANCE/APPLICATION

Quantitative susceptibility mapping can detect brain changes linked to age-related neuropathology, and may be a valuable diagnostic tool for age-related brain diseases.

SSE20-06 Whole Brain Structural Health in Relation to Cardiovascular Risk Factors: An Evaluation Using the Brain Atrophy and Lesion Index

Monday, Nov. 26 3:50PM - 4:00PM Room: E350

Participants

gutao001@hotmail.com

PURPOSE

Multiple structural changes on MRI in the brain can have interactive and additive impacts on aging and dementia. These changes can be collectively assessed using a semi-quantitative brain atrophy and lesion index (BALI). Previous studies have been focused on using the BALI to understand brain health of older adults, while it is not known how age and cardiovascular risk factors affect the accumulation of these various changes. In the present study, we address the question using a sample containing younger and middle-aged adults.

METHOD AND MATERIALS

Data of 239 subjects (men=71%; age range=20-80 years) who underwent regular health check and a routine anatomical MRI

examination in Beijing Hospital of China were analyzed. Basic demographics and traditional cardiovascular risk factors (CVRF) of the subjects were reviewed. A BALI score was generated for each subject by evaluating T2 weighted MRI at 1.5T and 3T. Mean difference in BALI total and subcategory scores between subjects of difference age and CVRF conditions were examined using t-test and ANOVA, while associations between the BALI score and age or CVFR was evaluated by correlation and regression analyses.

RESULTS

Over 89% of these subjects had at least one CVRF, while respectively 29%, 18%, 11%, 1% had two to five CVRFs. On average, older subjects had more CVRF. The BALI total score and subcategory scores were closely related to age (r's=0.41-0.69, p's<0.001). The BALI total and the categorical scores differed significantly by the number of CVRF (t's=4.16-14.83, p's<0.05). Subjects with a higher BALI score were more likely to be associated with at least one CVRF (X2's=6.9-43.9, p's<0.05). Multivariate analyses adjusting for various possible confounders demonstrated a strong impact of the CVRF on whole structural brain health as evaluated using BALI (Odds Ratio = 1.676, 95% CI=1.207-2.325), especially hypertension (OR=2.455, 95% CI=1.126-5.353), independent of the effect of age.

CONCLUSION

The accumulation of deficits in brain structure can start at a younger age. Cardiovascular risk factors play a key role in affecting such accumulation. The data emphasize the importance of early control of cardiovascular risk factors on promoting brain health in aging-and dementia.

CLINICAL RELEVANCE/APPLICATION

understand the relationship between age and whole brain structural health and how cardiovascular risk factors affect the accumulation of deficits in the brain over time using BALI

espoirhm@gmail.com

PURPOSE

To compare lesion detectability and the accuracy of risk stratification of skeletal survey, bone scan, and whole-body magnetic resonance imaging (WB-MRI) in patients with newly-diagnosed Langerhans cell histiocytosis (LCH).

METHOD AND MATERIALS

Patients who presented with newly-diagnosed LCH and who underwent skeletal survey, bone scan, and WB-MRI (n=46) between June 2011 and April 2017 were retrospectively included. The sensitivity and mean number of false-positives per patient in the three whole-body imaging modalities (skeletal survey, bone scan, and WB-MRI) were assessed. Risk stratification was performed in each patient for each whole-body imaging modality. The reference standard for LCH lesions was histopathologic findings or clinical and imaging follow-up. The ability to detect LCH lesions and the accuracy of the initial risk stratification were compared between the three whole-body imaging modalities.

RESULTS

WB-MRI had significantly higher sensitivity (99.0%; 95% confidence interval [CI], 93.2-99.9%) than skeletal survey (56.6%; 95% CI, 46.7-66.0%; p<0.0001) and bone scan (38.4%; 95% CI, 29.4-48.3%; p<0.0001) in the detection of LCH lesions, and there were no significant differences in the number of false-positives per patient (p>0.017 for all comparisons). WB-MRI tended to have higher accuracy for the risk stratification than skeletal survey and bone scan (concordance rate of 0.98, 0.91, and 0.83, respectively), although the differences between imaging modalities were not statistically significant (overall p-value 0.066).

CONCLUSION

WB-MRI had higher detectability for LCH lesions than skeletal survey and bone scan, while the three whole-body imaging modalities had comparable accuracy in the initial risk stratification of LCH.

CLINICAL RELEVANCE/APPLICATION

WB-MRI might serve as a primary imaging modality for risk stratification in patients with initially diagnosed LCH.

SSE21-02 The Complementary Role of Early Interim PET Semi-Quantitative Metrics to Lugano Criteria in Predicting Treatment Response in Children with Hodgkin Lymphoma

PURPOSE

To evaluate if adding iPET semiquantitative metrics to Lugano criteria will increase its predictability for response to therapy.

METHOD AND MATERIALS

112 children with newly diagnosed Hodgkin lymphoma between January 1, 2007 and January 1, 2017 underwent PET before treatment, after 2 cycles, and at the end of first line treatment. The diagnostic test accuracy of semi-quantitative metrics results were compared to Lugano criteria for assessment of treatment response at iPET time point to predict the final response to treatment. The standard of reference for treatment response was based on clinical assessment, imaging results at end of first line of treatment, and histopathological confirmation of residual masses. The group of patients with positive iPET as per Lugano criteria had been re-classified into positive and negative iPET as per semiquantitative metrics cut offs.

RESULTS

Using the Lugano criteria, 41 patients were positive and 71 were negative at iPET with accuracy of 70 %.Using semi-quantitative metrics, the number of positive cases decreased to 34 cases with a higher accuracy of 75%. On further analysis of the 41 positive iPET patients detected by Lugano classification, the number of positive cases decreased to 23 after applying our proposed cut offs for each of the semi-quantitative metrics. Thus,18 patients were reclassified as good responders according to semiquantitative analysis.

CONCLUSION

Semiquantitative metrics proved to be more accurate than Lugano criteria in prediction of treatment response at interim timepoint. Patients with positive iPET results according to Lugano classification may require additional evaluation using semi-quantitative metrics that classify the patients into groups with different outcomes. Larger prospective cohort and longer duration follow up is needed to support our claim.

CLINICAL RELEVANCE/APPLICATION

Therapeutic protocols for Hodgkin lymphoma have recently employed a response adapted approach with de-escalation of therapy for those patients with adequate interim response to avoid late effects of therapy. Definitions of adequate response have tended to be conservative to avoid undertreatment for a disease with excellent cure rates. The addition of semi-quantitative analysis may be helpful in therapy planning by identifying a larger pool of patients that may be eligible for de-escalation compared to the Lugano criteria.

SSE21-03 Value of Superb Microvascular Imaging in Biopsy Site Selection of Pediatric Solid Tumor

Monday, Nov. 26 3:20PM - 3:30PM Room: E353B

joychen1266@126.com

PURPOSE

To investigate the value of superb microvascular imaging (SMI) in biopsy site selection in children with solid tumor.

METHOD AND MATERIALS

A total of 48 children with solid tumors scheduled for biopsy were recruited in this retrospective study with mean age 4.58±3.62y (0.08-15y). All patients underwent CDFI/ CDE and SMI to image tumor vascularity using Adler criteria for biopsy site selection. Ultrasound guided biopsy was performed targeting hyper-vascularity region on SMI within 3 days following ultrasound evaluation. Another 35 patients with mean age 5.6±3.2y (1.6-15y) underwent CDFI/ CDE targeted biopsy between July 2012 and March 2015 were served as historical control. The sample adequacy of these two groups was compared retrospectively.

RESULTS

The Adler grade of 48 solid tumors using CDFI/ CDE was as follows: 2 tumors with grade 0 (4.2%, 2/48); 16 with grade I (33.3%, 16/48); 16 with grade II (33.3%, 16/48) and 14 with grade III(29.2%,14/48). By applying SMI technology, no tumor was scored with grade 0, one patient with grade I (2.1%, 1/48), 8 with grade II (16.7%, 8/48) and 39 with grade III (81.3%, 39/48). SMI was more sensitive in imaging tumor vascularity than CDFI/ CDE ($P<0.001$). The pathologic diagnosis was confirmed in all 48 tumors evaluated with SMI technology with sample adequacy of 100% (48/48). In comparison, the pathologic diagnosis was confirmed in 31 tumors in control group with sample adequacy of 88.6% (31/35, $P=0.025$). The biopsy was sampled in necrosis regions in 4 tumors in control group, and the final pathologic diagnosis was then confirmed by further surgery.

CONCLUSION

By increasing micro vessel display, SMI technology provides a practical solution to the problem of biopsy site selection in children with solid tumor. The biopsy site selected by SMI can avoid sampling necrosis or fibrotic regions and thus improve sample adequacy.

CLINICAL RELEVANCE/APPLICATION

For children with unresectable solid tumor, biopsy pathology is the standard approach for further treatment decision. The biopsy guided by SMI can avoid sampling necrosis or fibrotic regions, and thus reduce false negative results.

SSE21-04 Does Ferumoxytol Detect Joint Infiltration of Pediatric Cancer Patients?

PURPOSE

During our MR imaging evaluations of pediatric cancer patients with the iron oxide nanoparticle compound ferumoxytol (Feraheme), we observed a surprising marked T1-enhancement of the joint effusion in some patients and not others. The purpose of this study was to elucidate the underlying pathological mechanisms that lead to the observed ferumoxytol-induced indirect arthrography effect.

METHOD AND MATERIALS

We retrospectively identified 13 pediatric cancer patients and young adults (mean age 17.1 ± 4.1, 8 males, 5 females) with bone sarcomas (n=12) and desmoid tumor (n=1) who had undergone MRI scans at 1 hour (n=8), 24 hours (n=6) or 48-120 hours (n=1) after intravenous injection of ferumoxytol at a dose of 5 mg Fe/kg body weight. The patients received a whole-body MRI with T1-weighted LAVA sequences, followed by a local MRI with T1-SE, T2-FSE and LAVA sequences. 6 of the 13 patients had also received a gadobutrol (Gadavist)-enhanced MRI. 8 of the 13 tumors were resected and underwent surgical and/or histopathological evaluation of joint invasion. The signal-to-noise ratio (SNR) of tumors with and without joint invasion was compared using a t-test and a $p<0.05$.

RESULTS

At 1 hour after ferumoxytol infusion, we did not observe enhancement of joint effusions and no significant difference in SNR ($p>0.05$), regardless of tumor infiltration status. At >24 hours post-contrast, four patients showed significantly increased SNR values ($p=0.002$) of the effusion compared to muscle as an internal standard on T1-weighted images. Two of these patients were diagnosed with joint infiltration histologically while two others who did not undergo resection showed signs of joint infiltration on imaging. The other three > 24-hour scans did not show significant enhancement of the effusion and showed no joint infiltration on histology. Standard gadobutrol-enhanced MR images did not show this differential signal effect.

CONCLUSION

This pilot study suggests that ferumoxytol leak into a joint effusion might serve as an indirect indicator for joint infiltration in pediatric cancer patients. Further studies have to prove this finding in a larger cohort of patients.

CLINICAL RELEVANCE/APPLICATION

Ferumoxytol-enhanced MRI can detect joint infiltration in pediatric cancer patients.

SSE21-05 Ferumoxytol Does Not Impact SUV Values on PET/MR Scans

Monday, Nov. 26 3:40PM - 3:50PM Room: E353B

PURPOSE

Accurate measurement of standardized uptake values (SUV) of tumors and normal organs in positron emission tomography (PET) is crucial for treatment response assessment of pediatric cancer patients. The iron oxide nanoparticle compound ferumoxytol can be used "off label" as a contrast agent for integrated PET/MR scans. However, ferumoxytol accumulation in the reticuloendethelial system (RES) could affect MR-based attenuation corrections of PET data. The purpose of our study was to compare SUV values of normal organs on ferumoxytol-enhanced and unenhanced 18F-FDG PET/MR scans.

METHOD AND MATERIALS

In this IRB approved prospective study, 16 children (2-18 years) with malignant tumors underwent 18F-FDG PET/MR scans (dose 3 MBq/kg) before chemotherapy with (n=8) or without (n=8) intravenous injection of ferumoxytol (5 mg Fe/kg). Patients who received ferumoxytol were age- and sex-matched with patients who received unenhanced scans. MR attenuation correction was obtained by a four-point Dixon LAVA sequence accounting for fat, air, water, and soft tissue (TR 4.2 ms, TE 1.1, 1.7, 2.3 ms, FA 5). Anatomical correlation was obtained with a high-resolution LAVA (TR 4.4 ms, TE 1.1, 1.7, 2.2 ms, FA 15). For SUV mean values of normal organs three dimensional spherical region of interests were placed with MIM software over specified regions of the brain,

parotid gland, larynx, mediastinal blood pool, thymus, myocardium, liver, spleen, bone marrow, kidney and muscle and compared with a t-test.

RESULTS

The SUV mean values of patients with and without ferumoxytol-enhanced PET/MR scans were for brain (6.5 vs 6.4, p=0.96), parotid gland (1.3 vs 1.5, p=0.49), larynx (1.4 vs 1.6, p=0.14), mediastinal blood pool (1.4 vs 1.2, p=0.33), thymus (2.0 vs 2.0, p=0.76), myocardium (1.8 vs 1.7, p=0.44), liver (1.4 vs 1.6, p=0.67), spleen (1.7 vs 1.7, p=0.92), bone marrow (1.5 vs 1.8, p=0.12), kidney (2.0 vs 1.7, p=0.34), and muscle (0.5 vs 0.7, p=0.23). None of the organs or tissues showed a statistical significant difference.

CONCLUSION

Ferumoxytol at a dose of 5 mg Fe/kg has no impact on the SUV mean values of normal organs on PET/MR.

CLINICAL RELEVANCE/APPLICATION

Ferumoxytol can be used as a contrast agent in pediatric whole body PET/MR scans without impacting the SUV values of normal tissues.

SSE21-06 Voxel-Based Volumetric Analysis of Cortical Asymmetry in Glucose Metabolism in the Developing Human Brain

PURPOSE

Clinical interpretation of cerebral positron emission tomography with 2-deoxy-2[F-18] fluoro-D-glucose (FDG-PET) images often relies on evaluation of regional asymmetries. This study was designed to establish age-related variations in regional cortical glucose metabolism asymmetries in the developing human brain.

METHOD AND MATERIALS

FDG-PET scans of 58 children (age 1-18 years) were selected from a tertiary care single center pediatric PET database. All children had a history of epilepsy, normal MRI, and normal pattern of PET glucose metabolism on careful visual evaluation. PET images were analyzed objectively by statistical parametric mapping with the use of age-specific FDG-PET templates. Regional FDG uptake was measured in 35 cortical regions in both hemispheres using an automated anatomical labeling atlas, and left-to-right metabolic ratios of homotopic regions were correlated with age, gender, and epilepsy variables.

RESULTS

Regional cortical glucose metabolism was mostly symmetric in young children and became increasingly asymmetric in older subjects. Specifically, several frontal cortical regions showed an age-related increase of left>right asymmetries, while right>left asymmetries emerged in posterior cortex (including portions of the occipital, parietal and temporal lobe) in older children. Similar trends were seen in a subgroup of 39 children with known right-handedness. Age-related correlations of regional metabolic asymmetries showed no robust gender differences and were not affected by epilepsy variables.

CONCLUSION

These data demonstrate a region-specific emergence of cortical metabolic asymmetries between age 1-18 years, with left>right asymmetry in frontal and right>left asymmetry in posterior regions. These findings can facilitate correct interpretation of cortical regional asymmetries on pediatric FDG-PET images across a wide age range.

CLINICAL RELEVANCE/APPLICATION

Our findings will help in understanding the regional neurometabolic evolution and its relationship with neurocognitive development and its impairment in various neurological conditions.

CONCLUSION

This study showed widespread vertical off-centering across all sites and for all CT protocols. The effectiveness of individualized training of technologists is demonstrated by the significant ($p < 0.0001$) reduction in cases where patients were placed vertically off-center, as compared to the insignificant reduction following the classroom style annual training.

Background

Due to technological innovations, many aspects of CT systems have become automated to optimize patient dose and image quality. However, for some CT vendors, patient centering, which is critical for the proper performance of automatic exposure control, still remains a manual task. We sought to assess the frequency of patient vertical off-centering across the institution. We also investigated the effectiveness of methods used to re-educate technologists on optimal CT imaging practices.

Evaluation

Using a commercially available automated dose monitoring system (ADMS) (Dose Watch, GE), CT scan acquisition data for all protocols was collected from 12 CT scanners beginning in January 2017. The scanners were located at the main cancer hospital (n=3) and at 6 affiliated outpatient locations (OPL)(n=9). Data on vertical centering within the CT gantry were sorted by scanner location and operator. Comparisons of vertical off-centering were made across all locations. Re-education about optimal CT imaging practices was performed with each technologist at 1 OPL. The staff at the main cancer hospital and 6 other OPL received classroom-style annual training on optimal CT imaging practices.

Discussion

During the 2nd quarter of 2017, out of a total of n = 22708 patients, 50.5% percent of patients (n=11469) undergoing CT scans were positioned vertically off-center by a range of -11.8 cm to 10.9 cm, with a median (interquartile range) of 0.818 cm (-0.491 to 2.13 cm). Of these, 34.9% (n=7921) were scanned at OPLs. After individualized re-education with technologists at one OPL, patient vertical off-centering at that site decreased by 31.8% in the 3rd quarter. For all other locations where a classroom style annual training was delivered, a reduction of 1% in vertical off-centering was observed.

SSE22-02 Optimizing CT Image Characteristics Using a Large Data Set from Annual Medical Physics Performance Evaluations

For information about this presentation, contact:

david.jordan@uhhospitals.org

PURPOSE

This work determines typical image reconstruction and display settings for CT imaging and compares them to the reference values published by the AAPM.

METHOD AND MATERIALS

Scan protocol parameters were collected from reports of 100 annual CT scanner medical physics surveys in two states for adult head and abdomen and pediatric head and abdomen protocols per the ACR accreditation procedures. Data collection spanned academic and community hospitals and freestanding imaging centers; the data set includes pooled data collected by academic and consulting medical physicists. Reconstruction kernel/algorithm, image thickness, and image interval were tabulated for four protocols for all scanners; subgroups were analyzed to compare scanner manufacturers and different types of imaging facilities. Values were compared to reference protocols published by AAPM and recommended and required parameters given in the ACR CT Accreditation Clinical Image Quality Guide.

RESULTS

Protocols for CT scanners at ACR-accredited facilities adhered to the maximum slice width values specified by the ACR accreditation program. There was variability in adherence to AAPM-recommended reference parameters, ranging from 80% agreement for adult head protocols to 44% agreement for pediatric abdomen protocols. There was wide variation in the chosen reconstruction algorithm; subgroups were used to compare protocols within each manufacturer since direct comparison between different manufacturers' proprietary algorithms was not possible within the scope of this work.

CONCLUSION

There is substantial variation in image reconstruction parameters among ACR-accredited CT facilities that conform to ACR requirements. These parameters impact key image quality characteristics and radiation doses used for imaging, so appropriate choices are crucial to achieving optimization of imaging. Further work is needed to understand the nature of the deviation between the data collected at clinical sites and the AAPM reference protocols; while the AAPM protocols were published relatively recently, it is not clear whether the standard practice reflects changes that run ahead of updates to the AAPM protocols or whether the community is lagging in adopting the AAPM recommendations.

CLINICAL RELEVANCE/APPLICATION

This work validates reference CT protocols against protocols used in real imaging departments. Deviations from reference protocol can be used in troubleshooting image quality.

SSE22-03 CT Resolution, Noise, and Dose Reference Levels Across a Multi-Center Patient Population

Monday, Nov. 26 3:20PM - 3:30PM Room: S504AB

Participants

Ehsan Samei, PhD, Durham, NC (*Abstract Co-Author*) Research Grant, General Electric Company; Research Grant, Siemens AG; Advisory Board, medInt Holdings, LLC; License agreement, 12 Sigma Technologies; License agreement, Gammex, Inc

For information about this presentation, contact:

taylor.smith@duke.edu

PURPOSE

The diagnostic reference level (DRL) is useful as a first-order tool to compare radiation exposures of one's imaging clinic against those of one's peers in computed tomography. Ria et al. have advocated for the addition of a Noise Reference Level (NRL), Noise Reference Range (NRR), a Dose Reference Level (DoRL) and a Dose Reference Range (DoRR) as a means of extending the first steps of optimization of clinical operation to image quality in addition to radiation exposure (ICRP 135). In this work, we investigate and establish another reference level, for the case of resolution, called the Resolution Reference Level (RRL) and Resolution Reference Range (RRR).

METHOD AND MATERIALS

Over 10000 anonymized scans were sampled from 109 institutions in the United States which represented 13 large (estim. > 36,000 scans/yr), 32 medium (6000 - 36,000), 64 small (< 6000) imaging centers. CTDIvol, Noise and resolution (MTF) were measured for chest and abdominopelvic (AP) helical single-acquisitions of the trunk (extremity/head scans, multiple reconstructions excluded). Noise was taken as a modified version of the Global Noise Level measured in air. MTFs were measured from the air-skin interface. Patients were binned by their effective diameter. DoRL, NRL, and RRLs were measured for each size bin. Reference Levels for each were defined as the median values. Reference Ranges were defined as interquartile intervals.

RESULTS

Measurements of the f50 MTF in AP exams in all sizes had RRR lower bounds from 0.33 - 0.42 mm^{-1}. The RRR upper bounds for these exams ranged from 0.38 - 0.46 mm^{-1}. In chest exams these ranges were from 0.39 - 0.42 mm^{-1} and 0.45 - 0.46 mm^{-1} respectively. The lower bound of DoRR in the AP exams in all sizes ranged from 5.3 - 11.2 mGy. The upper bounds of DoRR ranged from 7.4 - 16.5 mGy. In chest exams these lower and upper bounds of the DoRR ranged from 5.4 - 11.5 mGy and 7.5 - 14.4 mGy.

CONCLUSION

An extension to the reference level methodology has been proposed. With this new RRL and RRR, and existing NRL, NRR, DoRL, and DoRR, a clinic can begin to make holistic decisions regarding population-based imaging-protocol adjustments with consideration to dose, noise, and resolution.

CLINICAL RELEVANCE/APPLICATION

This work extends the notion of NRL to the assessment of resolution. It represents a more generalizable sampling, with more vendors and kernels, and an order of magnitude increase in population.

SSE22-04 Image Quality Metric Extraction Based on Machine Learning Techniques for Clinical CT Protocol Optimization

Monday, Nov. 26 3:30PM - 3:40PM Room: S504AB

yin@research.ge.com

PURPOSE

To extract standard image quality metrics (image noise and spatial resolution) directly from clinical CT images using machine learning techniques. This capability is desired to guide optimization and customization of clinical protocols to achieve desired diagnostic image quality and clinical task performance.

METHOD AND MATERIALS

For training and testing of the machine learning networks, we acquire a series of clinical datasets and use post-processing techniques to generate datasets with various noise levels and various spatial resolution levels. We use the full-width-at-half-maximum (FWHM) of the point spread function (PSF) as spatial resolution metric and the standard deviation of the noise as image noise metric. 9 cardiac acquisitions with 224 images are post-processed to create various (5) levels of blurring, resulting in a combined training and test set of 10,080 images. We use both feature-based machine learning techniques and deep convolution neural networks (CNN) to execute supervised learning to estimate traditional analytic IQ metrics such as noise and spatial resolution. For example, to demonstrate the feasibility of the framework, we selected and implemented random forest regression approach for the supervised learning task. 7 features are extracted from the raw image and 8 features are extracted from the edge map. We extend this framework to deep convolution neural network (CNN) based machine learning method using Keras

RESULTS

Mean and standard deviation of estimation error is (0.0003mm, 0.0352mm) where true FWHM was emulated at [0.66mm, 1.174mm]. The figure below shows two example results: (a) an emulated image with a FWHM of 0.77 mm and the corresponding estimated FWHM has an error of 1.6%; (b) an emulated image with a FWHM of 1.02 mm and the corresponding estimated FWHM has an error of 4.7%.

CONCLUSION

It is feasible to extract image quality directly from clinical images. Both feature-based machine learning techniques and deep learning techniques are implemented and evaluated. Preliminary results show an accurate estimation of image quality with average errors of 3%.

CLINICAL RELEVANCE/APPLICATION

IQ estimation directly from clinical images is a critical enabler to guide optimization and customization of clinical protocols to achieve desired diagnostic image quality and clinical task performance.

SSE22-05 Predicting Major CT Scanner Failures Using Routine Quality Control Data

Monday, Nov. 26 3:40PM - 3:50PM Room: S504AB

Participants

Atallah Baydoun, MD, Cleveland, OH (*Abstract Co-Author*) Nothing to Disclose
David W. Jordan, PhD, Cleveland, OH (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

Rose.Alhelo@uhhospitals.org

PURPOSE

Data collected for daily equipment quality control (QC) on computed tomography (CT) scanners contain patterns that may predict near term failure of major scanner components. Such defects are usually time consuming and hamper significantly the clinical workflow. The purpose of this study is to identify, from determinable QC parameters, the key performance values that can predict scanner hardware failure.

METHOD AND MATERIALS

Our retrospective review included 37 CT scanners from four different manufacturers. Available QC data for all CT scanners included the daily records of mean and standard deviation (SD) of the CT number (HU) using the manufacturer's factory water phantom and a custom scan protocol. Data was stored in a cloud-based compliance solution and monitored using statistical process control according to our institution protocol. We identified two identical clinical CT units that had tube replacement within the last year. We collected the SD values over three month period before and after the replacement date. We then calculated the mean SD values before and after the repair for both units. We also determined pre- and post-repair cumulative SD and cumulative SD error relatively to each scanner mean SD.

RESULTS

The mean SD of the CT numbers (HU) before and after the tube replacement for CT1 were respectively 5.75 and 5.33 (Ratio=1.078) and for CT2 5.92 and 5.48 (Ratio=1.080). Pre-repair cumulative SD and cumulative SD error for CT1 were 517 and 745% and for CT2 538.9 and 842%. Post-repair cumulative SD and cumulative SD error for CT1 were 463.5 and 271% and for CT2

460.5 and 277%. The pre- and post-repair cumulative SD and SD error satisfy a linear model curve that correlates the QC measurements with the tube defect of both CT units.

CONCLUSION

Daily scanner HU noise values are insufficient to anticipate a major defect. However, a three-month cumulative SD and SD error above 500 and 700% respectively can predict failure of the tube component. Future studies are needed to highlight the possible use of such observed trends to predict impending failures. Thus, collection of data in an electronic database for a large scanner fleet would allow early intervention ultimately improving patient care.

CLINICAL RELEVANCE/APPLICATION

To our knowledge, this study is the first to introduce the cumulative SD and cumulative SD error as a predictive tool of a major CT performance failure.

SSE22-06 Realism and Potential of Population-Based Virtual Clinical Trials in Computed Tomography: Are We There Yet?

Monday, Nov. 26 3:50PM - 4:00PM Room: S504AB

PURPOSE

Medical imaging systems are currently evaluated using either physical phantoms or patient images, both with limitations. Physical phantoms are generally simplistic, not representative of a human population, and thus limited to fully reflect task-based or patient-specific assessments. Patient images are ground truth-limited, expensive, and ethically unattainable in repetitive studies. Virtual clinical trial (VCT), defined as conducting clinical experiments using realistic simulations, can overcome these challenges. This work aimed to develop a comprehensive package to conduct realistic VCT using realistic human models with known ground truth and representative CT imaging conditions.

METHOD AND MATERIALS

A realistic VCT requires two main toolsets: computational anthropomorphic phantoms and scanner simulators. We developed a series of high-resolution phantoms including highly detailed intra-organ anatomies. We also developed a rapid, realistic, and scanner-specific CT simulator to image the phantoms. Our simulator included geometry and physics (spectrum and bowtie filter) of commercial scanners, axial/helical trajectories, focal spot wobbling, poly/monochromacity, noise and detector response characteristics, scatter, tube current modulation, beam hardening correction, and a commercial processing box for scanner-specific reconstructions. Two pilot VCTs were performed: characterizing noise across reconstruction algorithms, and quantifying information loss as a function of beam collimation and pitch values.

RESULTS

Our simulator produced CT images with NPS, MTF, and HU values close to real CT scans of same physical phantoms, under different acquisition settings and reconstruction kernels. The pilot VCT showed that iterative images have non-stationary noise texture with higher noise magnitude in the edges.

CONCLUSION

We developed a package that conducts VCTs in the context of CT imaging and demonstrated its applicability in clinical studies where those studies need realistic heterogeneous models and repetitive measurements and therefore unattainable using physical phantoms or patient images. Our tool enables the imaging scientists and clinicians to explore and optimize the imaging systems more comprehensively.

CLINICAL RELEVANCE/APPLICATION

A realistic virtual clinical trial enables the medical imaging community to conduct clinically-relevant experiments that are impossible to perform using patient images or physical phantoms.

PURPOSE

To reduce cumulative radiation exposure and lifetime risks for radiation-induced cancer from breast cancer screening, we developed novel NNC deep learning for radiation dose reduction in DBT.

METHOD AND MATERIALS

Our original NNC deep learning employed patched-based neural network regression in a convolutional manner to convert lower-dose (LD) to higher-dose (HD) tomosynthesis images. We trained NNC with quarter-dose (25% of the standard dose: 12mAs at 32kVp) raw-projection images and corresponding "teaching" higher-dose (HD) images (200% of the standard dose: 99mAs at 32kVp) of a breast cadaver phantom acquired with a DBT system (Selenia Dimensions, Hologic). Once trained, NNC no longer requires HD images. It converts new LD images to images that look like HD images; thus the term "virtual" HD (VHD) images. We reconstructed tomosynthesis slices on a research DBT system. To determine a dose reduction rate, we acquired 4 studies of another test phantom at 4 different doses (1.35, 2.7, 4.04, and 5.39mGy entrance dose). Structural SIMilarity(SSIM) index was used to evaluate the image quality. For further testing, we collected half-dose (50% of the standard dose: 32±14 mAs at 33±5 kVp) and full-dose (100% of the standard dose: 68±23mAs at 33±5kvp) images of 51 clinical cases with the DBT system at Univ. of Iowa Hospitals & Clinics. We evaluated resulting images in a blinded observer study with 35 breast radiologists to rate and distinguish blinded VHD and real full-dose DBT images.

RESULTS

NNC converted quarter-dose images (1.35mGy; SSIM: 0.88) of the testing cadaver phantom to VHD images with image quality (SSIM:0.97) equivalent to 119% dose images (6.41mGy), achieving 79% dose reduction. In our blinded observer study, 21(60%) of 35 breast radiologists either preferred VHD images over real full-dose images or could not distinguish between the two. The difference in image quality between the two was not statistically significant (P=0.37). The time required to process each study was 0.48 sec. on a GPU (GTX Titan Z, Nvidia).

CONCLUSION

Blinded observer study with 35 radiologists demonstrated that VHD images converted by our deep-learning technology were equivalent to full-dose DBT images. Our cadaver phantom experiment demonstrated 79% dose reduction.

CLINICAL RELEVANCE/APPLICATION

Substantial radiation dose reduction would benefit patients by reducing the lifetime risk of radiation-induced cancer from DBT screening.

SSE23-02 Centralized Physics QC Program for the ECOG-ACRIN TMIST Trial of Breast Tomosynthesis

martin.yaffe@sri.utoronto.ca

PURPOSE

To describe and provide preliminary results from a remote-monitoring QC program developed to provide assessment of quality and rapid feedback in a screening trial. The program is being used in the randomized TMIST trial of screening with breast tomosynthesis versus digital mammography. TMIST is expected to include 125 sites in the US and Canada and will recruit 164,986 women who will be imaged up to 5 times over 4 years.

METHOD AND MATERIALS

The QC program is based on imaging of phantoms by the technologist at each site and digital transmission to a central analysis server. Phantoms assess signal and noise properties, artifacts, spatial resolution and geometric fidelity of the imaging system. The analysis is performed automatically with results made available to technologists on a password protected web site. Technical information from the DICOM header, stripped of personal identifiers, from every clinical image is available for analysis of doses, exposure factors and compression parameters..

RESULTS

As of April 2018, initial QC data from 87 units at the first 29 TMIST sites were available, including de-identified screening mammogram header data from 60 units at the first 25 sites. The most frequent technical problems were due to electronic interference, dustlike artifacts and the compression force being reported in the header as '0. Problems were also noted due to duplication of image submission from the same individual as separate cases and noncompliance with the QC protocol. In addition, it was noted that digital detectors were occasionally replaced without technical documentation. This was accompanied by changes in signal-to-noise performance. Based on 881 examinations, the mean dose (CC + MLO) was 4.2 mGy for 2D digital mammograms and 8.2 mGy for tomosynthesis. The presentation will report on results up to November, 2018.

CONCLUSION

Use of a centralized remote data collection QC system reduces technologist labor at the site and reduces subjectivity in testing. This approach enables consistent analysis and rapid reporting of QC results.

CLINICAL RELEVANCE/APPLICATION

Sensitivity and specificity of breast cancer detection depend critically on the technical image quality. The credibility of the results from the TMIST trial requires that the image quality of both modalities is verified. In addition, experience from this trial will provide data to help define the essential elements of the standard QC program for tomosynthesis.

PURPOSE

While all current x-ray based breast imaging modalities rely on minimal differences in soft tissue x-ray attenuation (absorption contrast), phase-contrast imaging has the capacity to also visualise variations in x-ray refraction (phase contrast). For x-ray energies typically used in breast imaging, the phase contrast can be substantially larger than the absorption contrast, presenting an opportunity to improve soft tissue visualisation especially in mammographically dense breasts. The goal of this study was to evaluate the radiological quality of images produced by the x-ray propagation-based phase-contrast computed tomography (PB-CT) technique at two different x-ray energies in comparison to absorption-based CT images collected at the same radiation dose (4 mGy).

METHOD AND MATERIALS

Twenty-seven synchrotron-based CT images of a full-size breast mastectomy specimen were reconstructed. Nine images were absorption-based CT at 32 KeV, nine images were PB-CT at 32 KeV and nine were PB-CT at 38 KeV. A group of breast specialist radiologists and medical imaging experts compared the radiological quality of the three sets of images based on various image quality criteria. Visual grading characteristics (VGC) analysis was conducted and VGC curves were obtained. The area under the VGC curve (0<=AUCVGC<=1) was calculated as the measure of the difference in image quality between two compared sets of images.

RESULTS

The results show that the radiological quality ratings of PB-CT 32 KeV images were significantly higher than absorption-based CT images (AUCVGC=0.879, p<=.001) and PB-CT 38 KeV images (AUCVGC=0.795, p<=.001). The image quality ratings were not significantly different between PB-CT 38 KeV images and absorption-based CT images (AUCVGC=0.567, p=.076).

CONCLUSION

Phase-contrast PB-CT mammography can be used to produce images with substantially higher radiological quality compared to conventional absorption-based images, but this advantage appears to be dependent on beam energy. The results from this study should provide a strong basis for future experimental and clinical protocols for further optimisation of this novel and promising approach to breast imaging.

CLINICAL RELEVANCE/APPLICATION

PB-CT of the breast is expected to deliver improved image quality compared to current x-ray modalities and become a viable method for early diagnosis of breast cancer in the future.

SSE23-04 Evaluation of American College of Radiology (ACR) Mammography Accreditation Phantom Image Quality of a Grid-Less and Software-Based Scatter Correction Technology

Monday, Nov. 26 3:30PM - 3:40PM Room: S502AB

Participants
Anzi Zhao, MS, Cleveland, OH (*Presenter*) Nothing to Disclose
Katie Hulme, MS, Cleveland, OH (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the quality of ACR mammography accreditation phantom images acquired with a grid-less and software-based scatter correction technology - Progressive Reconstruction Intelligently Minimizing Exposure (PRIME).

METHOD AND MATERIALS

3 Siemens Mammomat Inspiration units with PRIME were utilized in this study. The same ACR phantom was imaged on all units. 20 2D phantom images were acquired on each unit using a phototimed technique (W/Rh, 28kVp, AEC segmentation off, dose level 'normal', exam tag 'QC RAW'), of which 10 were acquired with grid in position and 10 were acquired with PRIME. Mode of acquisition was varied in a random order. 10 additional PRIME images were acquired on one unit with a resolution test pattern to assess spatial resolution. Contrast-to-noise ratio (CNR), signal-to-noise ratio (SNR), and standard deviation (SD) of phantom images were evaluated using the method in Siemens quality control manual. Incident air kerma and average glandular dose (AGD) were measured and calculated for each exposure. A total of 60 phantom images were scored by 4 qualified medical physicists and 2 experienced mammography technologists on a diagnostic workstation in clinical viewing conditions, and using ACR phantom evaluation guidelines with demographics hidden.

RESULTS

With PRIME, all images failed CNR criteria (>=2) with significantly lower CNR and higher SD than grid-based images by as much as 43% and 23%, respectively; SNR was reduced by 2-4%; spatial resolution was unaffected at 7 mm/lp; AGD was reduced by up to 16%. Visual scoring by 6 viewers resulted in no significant difference between the two types of images. Minor degradation on average score of masses on PRIME images compared to grid-based images (4.1 vs 4.2) was noted on one unit. All viewers agreed on the notable difference in image appearance and noise texture when PRIME was employed.

CONCLUSION

PRIME didn't penalize ACR phantom scoring, although there was a significant degradation of CNR on PRIME images because of the increased noise. The clinical implications of differences in noise texture warrant further investigation. Although PRIME offers moderate dose savings, clinicians should still be aware of potential effects on image appearance.

CLINICAL RELEVANCE/APPLICATION

PRIME technology corrects scatter radiation and enables grid-less full-field digital mammography at lower patient average glandular

PRIME technology corrects scatter radiation and enables grid-less full field digital mammography at lower patient average glandular dose, with comparable image quality.

SSE23-05 Mammographic Compression Variability Increased after Removing Real-Time Pressure Indicator

m.g.vanlier@amc.nl

CONCLUSION

When replacing a paddle with a pressure indicator, in a group of technicians familiar with the indicator, by a conventional paddle, the variability increased significantly leading to more unfavorable over- and under-compression.

Background

A certain level of breast flattening in mammography is needed to obtain a high quality image. Generally accepted and quantifiable standards do not exists. Recent studies show that the level of compression pressure at exposure influences screening performance. Attempts are made to standardize the compression procedure by introducing pressure-based compression using a paddle equipped with a real-time pressure indicator. We aimed to study the impact on compression practice when replacing the pressure-based paddle with a conventional paddle without pressure indication in group experienced technicians.

Evaluation

Mammographic compression pressure was retrospectively obtained from mammographic images (VolparaAnalytics) and evaluated in two datasets from the same radiology department with the same technician team. The first dataset (4 years, n=11.561 compressions) was collected when using a compression paddle equipped with a real-time pressure indicator aiming for a 10kPa (75mmHg) compression pressure. The second dataset (3 months, n=1331 compressions) was collected 4 months after the mammography system with pressure indicator was replaced by a system without pressure indicator. The average compression pressure and variance significantly ($P<0.001$) increased from 11.23 ± 0.04 kPa to 11.60 ± 0.14 kPa (mean ± SEM) after removal of the pressure indicator. The proportion of compressions in the pressure range 5-15 kPa decreased from 87.4% to 77.9%. The proportion of high pressures (>15kPa) almost doubled (11.0% to 18.8%) and low pressures (<5kPa) more than doubled (1.6% to 3.3%).

Discussion

When removing the pressure indicator, the initially low variability is increasing rapidly, indicating that an indicator is needed to remain high compression reproducibility. An increase in over- and under-compression can ultimately lead to decreased mammographic performance.

SSE23-06 Development of Low Dose Digital Mammography Platform by Image Reconstruction Using Deep Learning Algorithm: A Preliminary Study

Monday, Nov. 26 3:50PM - 4:00PM Room: S502AB

Participants
Su Min Ha, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose
Eunhee Kang, Daejon, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Jong Chul Ye, PhD, Daejon, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose
Hak Hee Kim, MD, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To investigate whether low dose mammography can be reconstructed to standard dose mammography using the new deep learning algorithm.

METHOD AND MATERIALS

14 specimens from 14 patients who underwent total mastectomy for primary breast cancer were included. Specimen mammograms were obtained with standard routine dose and reduced sequential doses; 80% of routine dose, 60%, 40%, 20% and 10%. The proposed de-noising method is designed based on semi-supervised learning with cycle consistency loss. Most of the mammography has Automatic Exposure Control (AEC) system which chooses an appropriate current X-ray source. The routine dose and 20% dose level images were selected as training dataset. Since the noise levels between two images are different and unavoidable slight mismatch due to potential deformation between multiple acquisitions, we developed the semi-supervised learning using cyclic consistency. We trained two generators (network G and F) and two discriminators (network Dx and Dy). Since we had 14 datasets, we performed cross-validation. Last, image quality of reconstructed low dose image was compared with the standard full dose image and was qualitatively rates as follows; 1= poor, 2= fair, 3= equal, 4=better.

RESULTS

As more radiation dose was decreased, noise was increased and contrast resolution was decreased accordingly. However, in the reconstructed images, noise was decreased and contrast resolution was rather improved. Overall, when we evaluated the lesions according to Breast imaging-reporting and data system lexicon, and with consideration of underlying breast parenchyma density,

the reduced dose of 20% cut-off of standard full dose showed no significant difference in image quality compared with standard dose mammography.

CONCLUSION

The image quality of reconstructed low dose mammography using the new deep learning algorithm is comparable with standard dose mammography until dose reduction cut-off 20% of standard full dose. Therefore, the radiation dose of mammography could be considerably reduced using this deep learning algorithm.

CLINICAL RELEVANCE/APPLICATION

Image reconstruction using the new deep learning algorithm is effective in dose reduction of mammography, especially in young women with high risk who are routinely examined with mammography for screening.

PURPOSE

To investigate the change of IVIM quantitative parameters before and after clinical treatment of patients with diabetic nephropathy, and objectively evaluate the clinical therapeutic effects of patients with diabetic nephropathy.

METHOD AND MATERIALS

20 patients(average age 56.60±9.38)with diabetic nephropathy who were diagnosed with diabetic nephropathy and received systemic hospitalization were selected. The clinical symptoms of the patients after treatment were significantly improved. The IVIM(b=0,50,100,150,200,400,600,800sec/mm²) and Diffusion weighted imaging(DWI,b=50,800 sec/mm²) sequence were obtained on a 3T scanner(Skyra, Siemens Healthineers). A total of 12 regions of interest were mapped in the cortex and medulla region of the upper pole, the renal hilum and the lower pole of the kidneys, and the results were averaged to obtain the measurement results.ADC map was automatically generated on the Siemens MRWP workstation after DWI sequence executed. IVIM parameters(ADC,D,f, and D* values) were generated by using a prototype software body diffusion toolbox(Siemens healthineers).Paired-sample t-test was used to compare changes in renal cortex and medulla ADC, D, f, and D* values before and after treatment in patients with diabetic nephropathy.

RESULTS

Compared to pre-treatment, ADC, D, f, and D* values of both kidney and medulla in patients with diabetic nephropathy were significantly higher ($p < 0.0001$) (Figure 1,Table 1).

CONCLUSION

IVIM is feasible for the evaluation of the efficacy of diabetic nephropathy, and it is helpful for the monitoring of clinical efficacy.

CLINICAL RELEVANCE/APPLICATION

IVIM responds to changes in the microstructure of the tissue, more scientific and objective assessment of clinical efficacy of diabetic nephropathy, with potential clinical application value.

SSE24-02 Diffusion-Weighted Imaging and Diffusion Kurtosis Imaging in the Diagnosis of Prostate Cancer: A Preliminary Retrospective Study

PURPOSE

This study explored and compared the value of DKI with DWI in distinguishing prostate cancer from non-cancer tissues and compared their performances in the peripheral zone and the central lobe.

METHOD AND MATERIALS

A retrospective review was performed in 212 consecutive patients who underwent examination on a clinical 3T MR scanner , and all patients were confirmed by pathology. A multi-b DWI sequence was performed with the following parameters: TR/TE = 5100/89ms, FOV = 280x224 mm2, scan,slice thickness = 4mm, slice number = 20, bandwidth = 1755Hz/Px, iPAT factor = 2, b-values =0, 500, 1000, 1500, 2000 mm2/s, scan time = 4min10s. Mean kurtosis (MK), mean diffusivity (MD) derived from DKI and apparent diffusion coefficient (ADC) derived from conventional DWI were calculated and analyzed by using an in-house-developed software based on MATLAB (Mathworks, Natick MA). The diagnostic accuracy of MK, MD and ADC values was evaluated with sensitivity, specificity, and area under receiver operating characteristic (ROC) curve (AUC). Student's t-test and ROC curves were used for statistical analysis.

RESULTS

There was a significant difference between non-cancerous tissues in the peripheral zone and central lobe (P <0.001) for MK, MD and ADC; while these parameters show no significant difference between prostate cancers in the peripheral zone and the central lobe (p>0.05). For the peripheral zone, MK, MD and ADC had sensitivities of 0.980, 0.983, 0.993, specificities of 0.994, 0.988, 0.993, and AUCs of 0.9996, 0.9993, 0.9998 when using cutoff values of 0.701, 1.693x10-3mm2/s, and 1.141x10-3mm2/s, respectively. While for the central lobe, the diagnostic performance of MK, MD and ADC dropped and got sensitivities of 0.785, 0.843, 0.855, specificities of 0.983, 0.978, 0.981, and AUCs of 0.9430, 0.9571, 0.9569, when the cut-off points were 0.829, 1.527x10-3mm2/s, 0.997x10-3mm2/s, respectively.

CONCLUSION

DKI and DWI may depict microstructure changes of prostate cancer, and can potentially provide quantitative information for the prostate tissue and have similar good diagnostic performance to distinguish prostate cancer from non-cancer tissues. the diagnosis values in the peripheral zone were slightly better than in the central lobe.

CLINICAL RELEVANCE/APPLICATION

DKI and DWI both could be used in clinical for distinguishing prostate cancer from non-cancer tissues, and would lead to a substantial improvement in the diagnosis of prostate cancer.

SSE24-03 The Susceptibility of Thrombus in Middle Cerebral Artery Predicts Prognosis by Quantitative Susceptibility Mapping

Monday, Nov. 26 3:20PM - 3:30PM Room: S504CD

Shuang Xia, MD, Tianjin, China (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

zhengmeizhu163@163.com

CONCLUSION

The susceptibility remained consistent regardless the location, thrombus length and onset time, which indicated that the thrombus composition was similar when detected on SWI. Susceptibility, thrombus length and CBS could predict clinical severity and short-term clinical prognosis.

Background

The quantitative susceptibility mapping(QSM) is used to evaluate susceptibility, length of thrombus and clot burden score (CBS) in the middle cerebral arterial.

Evaluation

To explore the relationship between thrombus and cerebral infarction and to early clinically prognose patients with acute cerebral infarction by QSM. We analyzed the data of 73 patients with acute cerebral infarction who had unilateral middle cerebral arterial occlusion on time of flight magnetic resonance angiography (TOF-MRA), and had the corresponding susceptibility vessel sign (SVS) on susceptibility weighted imaging (SWI). Susceptibility, length of CBS were evaluated based on QSM. The relationships between susceptibility and thrombus length, CBS, DWI-ASPECTS, admission and discharge National Institutes of Health stroke scale (NIHSS) were analyzed. The susceptibility among different locations and different segments of the thrombi did not achieve statistically difference(All p>0.05). The susceptibility and length were negatively correlated with DWI-ASPECTS (R2=0.045,0.186, p=0.034,0.000) and positively correlated with admission NIHSS(R2=0.058,0.067, p=0.014,0.015). The susceptibility was positively correlated with discharge NIHSS(R2=0.096, p=0.036). CBS was negatively correlated with thrombus length, admission and discharged NIHSS (R2=0.177,0.133,0.042, p=0.000,0.006,0.019) and positively correlated with DWI-ASPECTS(R2=0.107, p=0.002).

Discussion

There were two main findings in this study. First, all the susceptibility remained consistent regardless of the different segments, locations and onset time. Second, susceptibility, length of thrombus and CBS correlated to the extent of cerebral infarction, and they could all independently predict clinical severity and short-term clinical prognosis apart from the effect of length of MCA thrombus to the discharge NIHSS.

PURPOSE

To characterize image quality and accuracy of highly accelerated Wave-CAIPI SWI compared to standard 3D SWI and 2D gradient-echo (GRE) for detection of intracranial hemorrhage.

METHOD AND MATERIALS

Optimization: Wave-CAIPI SWI was evaluated on a 3T Prisma MR scanner (Siemens, Erlangen) using 6-fold (acquisition time TA=1.5 min) and 9-fold (TA=1 min) acceleration on commercially available 20-channel and 32-channel RF coils. SNR was evaluated as a function of acceleration factor and head position in a healthy subject using the multiple acquisition method (NEX=10). *Clinical evaluation:* Wave-CAIPI SWI was prospectively compared to standard 3D SWI (TA=4.5 min) or 2D GRE (TA=2.3 min) for 63 consecutive patients undergoing clinical brain MRI. Two radiologists evaluated all images for the presence of hemorrhage, number of hemorrhagic foci, motion artifacts, and subjective image quality.

RESULTS

Adequate SNR (>30) was achieved in the central brain using 9-fold acceleration on the 32-channel coil and 6-fold acceleration on the 20-channel coil. Wave-CAIPI SWI was compared to standard SWI for 33 patients and 2D GRE for 30 patients. Inter-rater reliability was almost perfect for presence of hemorrhage (κ=0.92) and number of hemorrhages (κ= 0.89), substantial for motion artifact (κ=0.69), and modest for subjective image quality (κ=0.50). Motion artifacts in Wave-CAIPI SWI were less severe than standard SWI (p<0.01). Wave-CAIPI and standard SWI provided 100% agreement for presence of hemorrhage (13 of 33 patients). In two cases, additional hemorrhagic foci were detected on Wave-CAIPI SWI which were obscured by motion on the standard SWI. Wave-CAIPI SWI identified presence of hemorrhage in 13 of 30 patients compared to 11 of 30 patients for 2D GRE. In 6 cases, additional hemorrhagic foci were identified on Wave-CAIPI SWI that were not seen on the 2D GRE sequence. Subjective image quality was higher for Wave-CAIPI SWI than 2D GRE (p<0.01), and was not significantly different between Wave-CAIPI and standard SWI.

CONCLUSION

A 1 minute Wave-CAIPI SWI acquisition is comparable to a 4.5 minute resolution-matched standard SWI sequence and superior to a 2.3 minute 2D GRE sequence for detection of intracranial hemorrhage.

CLINICAL RELEVANCE/APPLICATION

Wave-CAIPI SWI may be useful to shorten clinical brain MR protocols, especially in motion prone populations. Acceleration should balance scan time with acceptable SNR for a given hardware configuration.

SSE24-05 5D Relaxation-Diffusion Tensor Correlation MRI for Model-Free Quantification of Microscopic Heterogeneity of Brain Tissue

Monday, Nov. 26 3:40PM - 3:50PM Room: S504CD

PURPOSE

Conventional quantitative MRI yields voxel-average relaxation rates and diffusion tensors that are difficult to interpret in terms of chemical composition and microstructure whenever the voxels contain more than one tissue type such as white matter (WM), gray matter (GM), cerebrospinal fluid (CSF), and tumor. Here we introduce a method to quantify per-voxel heterogeneity as joint relaxation and diffusion tensor distributions.

METHOD AND MATERIALS

We propose a data acquisition protocol and inversion procedure to estimate nonparametric 5D joint distributions with the dimensions transverse relaxation rate R2, isotropic diffusivity, normalized diffusion anisotropy, and diffusion tensor orientation (two dimensions). A healthy volunteer was scanned on a Siemens Prisma 3T system using a diffusion-weighted EPI sequence customized for variable echo times and tensor-valued diffusion encoding, giving a 5D acquisition space with dimensions directly corresponding to the ones of the sought-for distributions. A total of 852 images were acquired at 2x2x6 millimeter spatial resolution, 110x110 matrix size, 11 slices, and a total scan time of 45 min without using simultaneous multislice. Per-voxel distributions were obtained by unconstrained Monte Carlo inversion including uncertainty estimation.

RESULTS

Voxels containing pure WM, GM, or CSF give nearly single-mode distributions (WM: high R2, low diffusivity, high anisotropy; GM: high R2, low diffusivity, low anisotropy; CSF: low R2, high diffusivity, low anisotropy), while voxels with binary mixtures yield the corresponding bimodal distributions. Component-resolved maps of signal amplitude, R2, diffusivity, anisotropy, and orientation for the WM, GM, and CSF fractions are obtained by binning and parameter calculation in the 5D distribution space.

CONCLUSION

Our image acquisition protocol and model-free data inversion procedure yields per-voxel quantification of distinct tissue types without relying on assumptions about the number or properties of the individual components.

CLINICAL RELEVANCE/APPLICATION

The new method is expected to be useful for pathological conditions associated with sub-voxel tissue heterogeneity, e.g. tumor infiltration in surrounding brain tissue or replacement of myelin with free water.

SSE24-06 Susceptibility Artifact on Diffusion-Weighted Imaging for 3T Prostate MR: Effect of Rectal Gel on Image Quality

Monday, Nov. 26 3:50PM - 4:00PM Room: S504CD

CONCLUSION

Our preliminary data suggests that for patients undergoing 3T surface coil prostate MR, instilling rectal gel can successfully decrease susceptibility artifact from excess gas, resulting in improved visualization of the PZ and increased diagnostic confidence.

Background

While use of 3T surface coil examinations has led to increased patient comfort for prostate MR, elimination of the endorectal coil has resulted in new challenges. Susceptibility artifact from rectal gas can significantly limit visualization of the peripheral zone (PZ) on diffusion-weighted (DWI) images, potentially risking the detection of clinically significant cancers. Few studies have evaluated strategies to reduce this artifact, so we have piloted a method of instilling rectal gel in an attempt to displace excess gas.

Evaluation

We introduced a new workflow for real-time monitoring of prostate MR studies. If a marked amount of rectal gas or DWI susceptibility artifact was noted, 60 mL of ultrasound gel was administered per rectum, and images repeated. Between July 2017 and February 2018, 149 evaluations were performed at our institution, of which 26 cases with both pre- and post-gel DWI series were identified for retrospective analysis. Two subspecialty abdominal radiologists assigned 5-point scale values to assess the amount of PZ visualized (1=low, 5=high), PZ distortion by susceptibility artifact (1=low, 5=high), degree of rectal distention (1=none, 5=high), and overall diagnostic confidence (1=none, 5=without limitation). Both paired t-test and Wilcoxon rank-sum tests were performed to assess the effectiveness of the intervention. Rectal gas volumetry was also performed with segmentation of the estimated intraluminal space on T2-weighted images from the level of the prostatic base to the anorectal junction.

Discussion

PZ visualization and overall diagnostic confidence were increased for both readers to a statistically significant level ($p<0.05$). A corresponding decrease in perception of gas volume and decreased PZ distortion was also achieved to a statistically significant level ($p<0.05$). The administration of gel on average decreased rectal gas volume by 2-fold. Gel injection was well tolerated by all patients.

Yue Lv, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

The value of Ktrans in DCE-MRI in the diagnosis of pathological grade of cervical cancer

METHOD AND MATERIALS

Retrospective analysis of 19 patients with poorly differentiated and 15 moderately well-differentiated cervical cancers who were confirmed by surgery and pathology from September 2015 to February 2017 and preoperatively performed 1.5T MRT1WI, T2WI, DCE-MRI, DWI, and other MR examinations. DCE-MRI images were analyzed and measured by two observers using the GenIQ software on the ADW4.6 workstation. The consistency of the data was evaluated by using ICC. An independent sample t test was used to compare the difference in Ktrans values in DCE-MRI between poorly differentiated and moderately differentiated cervical cancers. The ROC curve was used to analyze the Ktrans value to identify the diagnostic efficiency of poorly differentiated and moderately differentiated.

RESULTS

The parameters measured by the two observers were in good agreement (ICC values >0.75). The Ktrans value of the poorly differentiated group was greater than the moderately high differentiated group (0.70±0.21 vs 0.52±0.20), and the difference was statistically significant (P<0.05). The Ktrans value >=0.68 is a diagnostic threshold for the diagnosis of poorly differentiated and moderately differentiated, corresponding sensitivity and specificity of 52.6% and 81.2%, and AUC is 0.717.

CONCLUSION

The value of Ktrans in DCE-MRI has a certain value in the differential diagnosis of poorly differentiated and moderately differentiated cervical cancer.

CLINICAL RELEVANCE/APPLICATION

The prognosis of poorly differentiated and moderately differentiated cervical cancer is completely different, and differential diagnosis is extremely important.

SSE25-04 Radiologic Assessment of Inguinal Lymph Nodes in Pelvic Malignancies

PURPOSE

Metastatic involvement of inguinal lymph nodes can alter radiation therapy (RT) planning for pelvic tumors. 18F-FDG PET/CT can identify metastatic nodes; however, inguinal nodes are commonly abnormal due to non-malignant processes such as infection or inflammation, complicating interpretation. We evaluated quantitative PET metrics to improve identification of metastatic inguinal nodes in patients with pelvic tumors compared to standard clinical interpretation.

METHOD AND MATERIALS

We identified 36 patients with vulvar cancer, 4 with vaginal cancer, and 14 with anal cancer who underwent 18F-FDG PET/CT prior to pathologic evaluation of inguinal nodes. For each groin evaluated pathologically, we analyzed the following values on the node with highest FDG uptake: maximum, peak and mean standardized uptake values (SUVmax, SUVpeak, SUVmean, respectively), total lesion glycolysis (TLG) and metabolic tumor volume (MTV). SUVmean, TLG and MTV were determined for volumes defined by thresholds of 42% and 50% of SUVmax, and for SUV >= 2.5. CT images were used to measure volume, short and long axes of each lymph node. Multivariate logistic regression identified predictive metrics for pathologic positive nodes and generated a probabilistic model. The AUCs of ROC curves for the model were compared to the standard clinical interpretation from the diagnostic report using adjacent pairwise differences.

RESULTS

Of 54 patients identified, 75 groins were evaluated pathologically resulting in 75 nodes for analysis (35 were positive for malignancy). Logistic regression identified SUVmean (50% threshold) and short axis length as most predictive for metastatic nodes. The model was better able to predict pathologic involvement compared to standard clinical interpretation (AUC: 0.91 [95%CI: 0.84 - 0.97] vs 0.80 [95%CI: 0.71 - 0.90], P<0.01).

CONCLUSION

18F-FDG PET/CT diagnostic accuracy for metastatic inguinal nodes in pelvic tumors may be improved with use of quantitative PET metrics and warrants further validation. Improving prediction of metastatic nodes can aid with appropriate selection of patients for pathologic node evaluation and guide RT volumes and doses.

CLINICAL RELEVANCE/APPLICATION

18F-FDG PET/CT accuracy for inguinal metastases may be improved with quantitative metrics for patients with pelvic malignancies and aid with radiation treatment planning.

SSE25-05 Assessment of MR Compatibility of Novel Needle Placement Template and Collets for Intraperitoneal Interstitial Gynecological Brachytherapy Application

christopher.tien@yale.edu

PURPOSE

A supplemental template kit was obtained to aid intraperitoneal needle implant geometry for MR-guided interstitial cervical brachytherapy. This product is in final stages of FDA approval and has not yet received MR-conditional designation. Therefore, our institution independently evaluated the MR compatibility using ASTM International guidelines and report our results.

METHOD AND MATERIALS

The supplemental kit consisted of the template (made of PEEK material with 40 6-Fr diameter holes) and 25 titanium collets. In the proposed clinical kit, the template and collets would be added to existing equipment including the cylindrical obdurator, tandem, and PEEK needles, which have been deemed MR-conditional previously. The planned fully-assembled applicator set is shown in Figure 1. A 3.0 T magnet was used to represent the most challenging MR environment as our institutional policy for MR-guided treatment planning is 1.5 T. Magnetically-induced effects of displacement force and torque were evaluated using ASTM F2052-15 and F2213-06 standard test methods, respectively. RadioFrequency (RF)-induced heating was evaluated using ASTM F2182-11a standard test methods. Final assessment for MR-conditional status was defined using ASTM F2503 requirements.

RESULTS

For the template and collets, the mean measured displacement was undetectable, there was no observed translation, no observed deflection, and no observed torque when placed at the strongest point of the magnet. Neither template nor collets were deemed candidates for RF-induced heating. The template was exempted based on its composition of 100% PEEK material. The collets were exempted as literature has repeatedly shown that devices smaller than one-tenth of the electromagnetic field (i.e. 5 cm for 1.5 T and 2.4 cm for 3.0 T) will not have a measurable rise in temperature.

CONCLUSION

ASTM International standards and guidelines were newly-acquired equipment. Standard test methods showed absence of any movement or torque, and complied with exemptions for RF-induced heating tests. Following ASTM F2503 guidelines, the equipment

is MR-conditional for 3 T, and thus is MR-conditional for 1.5 T.

CLINICAL RELEVANCE/APPLICATION

Novel brachytherapy applicator designed for MR-guided radiation therapy was tested internally by our institution to ensure MR compatibility and was deemed MR-conditional.

SSE25-06 3D MRI-Based Brachytherapy for Cervical Cancer: Can Dose Escalation Improve Survival?

Monday, Nov. 26 3:50PM - 4:00PM Room: S104B

Awards
Student Travel Stipend Award

Participants
Zachary D. Horne, MD, Pittsburgh, PA (*Presenter*) Nothing to Disclose
Ronny Kalash, Pittsburgh, PA (*Abstract Co-Author*) Nothing to Disclose
Sushil Beriwal, MD, Wexford, PA (*Abstract Co-Author*) Consultant, Varian Medical Systems, Inc

PURPOSE

Brachytherapy is an essential component of the treatment of locally advanced cervical cancer; recent GEC-ESTRO guidelines recommend that the dose to 90% (D90) of the high-risk clinical target volume (HRCTV) be at least 85Gy with even higher doses recommended to improve outcomes

METHOD AND MATERIALS

A retrospective review of brachytherapy plans delivered at a single institution were evaluated for dose parameters and local control following treatment. The HRCTV D90 was retrieved from all plans. Survival was defined as the interval between last brachytherapy fraction to time of death or last follow up. Significance of tumor parameters on survival was evaluated with uni- and multivariable Cox regression analysis.

RESULTS

A total of 250 women underwent high dose-rate brachytherapy for cervical cancer between 2007 and 2017 with evaluable dosimetry. Median follow up was 27.5 months. The median prescribed dose was 27.5Gy/5fx with a median HRCTV D90 of 83.9Gy (IQR: 81.9-85.7Gy), HRCTV volume of 31cc (IQR: 25.9-39.9cc), and treatment time of 7.3 weeks. Overall survival at 2 and 5 years was 84.9% and 72.4%. Factors which correlated with survival included age, initial tumor size, HRCTV D90, treatment time and HRCTV volume. On multivariable analysis, only HRCTV volume (HR 1.039 [95%CI 1.017-1.062], p=0.001), prolonged treatment time (HR 1.439 [HR 1.176-1.762], p<0.001), initial tumor size (HR 1.184 [95%CI 1.010-1.389], p=0.037), and age (HR 1.038 [95%CI 1.016-1.060], p<0.001) correlated with survival. HRCTV D90 approached significance with a higher D90 per Gy: HR 0.901 [95%CI 0.808-1.005], p=0.061. Survival at 2 and 5 years for women with tumors 31cc and less at the time of BT were 91.6% and 78.5% vs 78.3% and 66.0% for women with tumors greater than 31cc (p=0.026).

CONCLUSION

Survival is excellent with MRI-based planning in the entire cohort of patients. Our data suggests that adverse factors such as adenocarcinoma histology, large tumor, and poor response to chemoradiation cannot be overcome with dose escalation. The prospective EMBRACE II trial will further help us clarify the impact of dose escalation in poor responders.

CLINICAL RELEVANCE/APPLICATION

This suggests that different methods of therapeutic intervention are required for high-risk and poor-responding cervical cancer patients.

pyi10@jhmi.edu

PURPOSE

Prior studies have shown underrepresentation of people of African-American descent within multiple medical specialties. Interventional Radiology (IR) has traditionally been a white male-predominate field and it is unknown if race diversity in IR has improved over time. The purpose of this study was to analyze trends in representation of black trainees in IR in comparison with other related fields over the past 20 years.

METHOD AND MATERIALS

We reviewed data from the American Association of Medical Colleges reported in annual issues on medical education in JAMA for the years 1995-2015. We assessed the percentages of black trainees in IR fellowships and other training programs, including Diagnostic Radiology residency, Radiation Oncology residency, Pediatric Radiology fellowship, and Neuroradiology Fellowship, as well of Residents from all specialties. Changes in the percentages of black residents/fellows from 1995 to 2015 were calculated for each group using Chi-Square tests.

RESULTS

From 1995 to 2015, the percentage of black trianees in IR fellowship increased from 0% to 4% ($p=0.03$). Similarly, from 1995 to 2015, the percentage of black trainees in every other training program studied increased significantly; for example, black representation in residency (all specialties) improved from 5% to 6% ($p<0.0001$) [Image 1]. In 2015, IR had no significant difference in black trainee representation compared to the other training programs studied.

CONCLUSION

Although the percentage of black trainees in IR fellowship has significantly increased over the past 20 years and is commensurate with the general residency population, black trainees are under-represented compared to the general USA population (18%). We recommend increased recruitment efforts towards black trainees at different levels of training both during and after medical school to improve the diversity within IR and other fields.

CLINICAL RELEVANCE/APPLICATION

Although the percentage of black trainees in IR fellowship has significantly increased over the past 20 years, black trainees are under-represented compared to the general USA population.

SSE26-02 An Analysis of the Patient Population Seen in a Newly Established Interventional Radiology Ambulatory Clinic

agunn@uabmc.edu

PURPOSE

To analyze the types of patients seen in a newly established interventional radiology (IR) ambulatory clinic with an assessment of changes in that population over the clinic's first eight months of existence.

METHOD AND MATERIALS

A retrospective review of the clinic appointments that occurred in the first eight months was performed. Patient demographics, diagnosis, type of IR procedure for which they were being seen, and the type of visit (i.e new vs. return patient) were collected. Data points from the first four months (group 1) and second four months (group 2) of the clinic were analyzed separately to assess for any changes over time. A p value of <= 0.05 was considered statistically significant.

RESULTS

There were a total of 1,489 clinic visits in the first eight months (739 males; 750 females; mean age: 57.3 years). Overall, the three most common diagnoses were hepatocellular carcinoma (HCC) (14.3%, n=214), abscess (9.8%, n=146), and oropharyngeal cancer (8%, n=119). HCC, abscess, and oropharyngeal cancer were the three most common diagnoses for both groups 1 and 2 without a significant difference between groups. The three most common procedures performed on patients overall were chest port (24.9%, n=371), gastrostomy/gastrojejunostomy (20.6%, n=307), and chemoembolization (15.4%, n=229). Chest ports, gastrostomy/gastrojejunostomy, and chemoembolization were the three most common types of procedures performed on these patients in both groups 1 and 2 without any significant difference between the groups. There was also no significant difference between the groups for any other procedures performed, including: primary biliary drainage, IVC filter placement/retrieval, abscess drainage, uterine fibroid embolization, radioembolization, renal cryoablation, liver ablation, TIPS, kyphoplasty/vertebroplasty, or percutaneous sclerotherapy. Overall, 283 visits (19%) were "new" patient appointments. There was no significant difference between the groups in number of new patients seen (group 1: 18.4%, group 2: 19.4%; p=0.6).

CONCLUSION

IR sees a wide variety of patients in ambulatory clinic but the population did not change significantly during the sampling period.

CLINICAL RELEVANCE/APPLICATION

Ambulatory clinics can help IR establish itself as a clinical service. Information about the types of patients seen in these clinics can inform quality improvement and practice-building initiatives.

SSE26-03 Trends in Imaging Guidance for Percutaneous Procedures in the Medicare Population, 2007-2016

Monday, Nov. 26 3:20PM - 3:30PM Room: S104A

Participants
Ali B. Syed, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

Laurence Parker, PhD, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose
Vijay M. Rao, MD, Philadelphia, PA (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

ali.b.syed@jefferson.edu

PURPOSE

Imaging guidance has driven the rapid growth of percutaneous procedures. Our purpose was to assess utilization trends in imaging guidance for percutaneous procedures in recent years.

METHOD AND MATERIALS

The nationwide Medicare Part B databases for 2004-2016 were utilized. We selected the current procedural terminology (CPT) codes for CT, ultrasound (US), fluoroscopy (FL), and MRI guided procedures. CT, MRI, and FL codes were first introduced in 2007. The database provides volumes for each code. Medicare specialty codes were used to identify the specialty of the billing provider. Trend lines were plotted for total volume per year as well as for radiology and other major specialties per year. Because these databases represent a full population, sample statistics are not required.

RESULTS

US is the most common imaging modality used for guidance, followed by FL, then CT, and lastly MRI. Total volume of US guided procedures increased steadily from 864,008 in 2007 to 2,144,285 in 2016 (+148%). Orthopedic surgeons perform the highest proportion of US procedures (20% - mostly joint injections and aspirations), followed by anesthesia (19%) and then radiologists (9%). FL guidance has increased from 150,165 in 2007 to 495,273 in 2016 (+230%). Radiologists perform the highest proportion of these procedures (26%) among the individual specialties. CT guidance has remained relatively constant from 2007-2016 (196,473 to 204,063), with radiologists performing 98% of these procedures. MRI guidance volumes were very low, with radiologists performing 44%, followed by urologists at 39%. Total imaging-based guidance procedures (all modalities) increased from 1,220,749 in 2007 to 2,847,651 in 2016 (+133%).

CONCLUSION

Image guidance for procedures has grown since 2007. Radiologists perform more image-guided procedures than any other single specialty, although their overall share is only 19%. Ultrasound is the modality of choice for most procedures, accounting for over 75% of the image guidance for percutaneous procedures performed in 2016. Other specialties have increased their share of image-guided procedures since 2007, particularly of procedures with US and FL guidance.

CLINICAL RELEVANCE/APPLICATION

Radiologists perform the greatest proportion of image guided procedures, predominantly with US guidance, although other specialties have increased their usage of image guidance in recent years.

SSE26-04 Show Me the Money: Comparison of Political Action Committee Funding and Physician Compensation

junjian.huang@uphs.upenn.edu

PURPOSE

To compare physician compensation of specialties with a political action committee (PAC) to those who do not.

METHOD AND MATERIALS

Physician specialties were identified through the AAMC 2015 physician workforce survey as well as the Medscape 2017 physician compensation report. Compensation data was collected via Medscape compensation surveys from the years of 2011-2017, American Medical Group Association (AMGA), Pinnacle Group, and Doximity. All PAC related data was collected via opensecrets.org. Statistics were performed with SPSS (IBM).

RESULTS

A total of 31 physician specialties were included in the analysis. Nearly 90% (n=28) had a PAC,10% (n=3) did not. Averages of the following were calculated for each specialty from 2010-2016: physician compensation, PAC donation, and PAC expenditure. Average PAC donation and PAC expenditure per capita was also calculated. A direct linear correlation was found between average PAC donation and average PAC expenditure for all the physician specialties (R2 of 0.999). Specialties with a PAC demonstrated higher average compensation than those without a PAC ($328,700 vs. $211,500) with a mean difference of $117,000 (p=0.04). SIR has one of the most underfunded PACs. For comparison,vascular surgery PAC contributions is 1.5x that of SIR's and cardiology PAC boasts a 9x financial advantage over our own.

CONCLUSION

Advocacy is not just about compensation but the reality is that being paid what you deserve is important. Our analysis reveals that over the past decade, specialties with higher physician compensation tend to have larger, more well funded PACs. A well funded PAC allows for more PAC expenditure which grants better access to members of Congress. Considering IR has recently separated from diagnostic radiology, which boasts one of the most robust PACs on our list, the impact of having an underfunded political action committee is unknown but worrisome considering our direct competitors (cardiology and vascular surgery) dwarf us in comparison. Policy drives practice, if we are to be true competitors then awareness and support of our PAC is critical.

CLINICAL RELEVANCE/APPLICATION

Political awareness and activisim is critical to the success of a specialty and those with political action committees lobbying on their behalf earn substantially more than those who do not.

SSE26-05 Training by the Numbers: A Survey-Based Analysis of the Number of Positions Available in New Interventional Radiology Training Pathways

Monday, Nov. 26 3:40PM - 3:50PM Room: S104A

PURPOSE

The number and types of training pathways in interventional radiology (IR) have undergone a fundamental change, yet little is

known about the number of Independent IR (IndIR) positions relative to the number of positions in the Early Specialization in IR (ESIR) pathway. Thus, we investigate whether the number of available ESIR positions is aligned with the number of IIR positions.

METHOD AND MATERIALS

A three-question survey was conducted over e-mail and telephone to residency program directors and coordinators (Figure). Data collected included the number of ESIR, IntIR (Integrated IR), and IndIR positions, and number of current IR fellows accepted per year. Information was also obtained from publicly available databases on the SIR, ACGME, and ERAS websites. Analysis of results was performed using Microsoft Excel (Microsoft, Redmond, VA).

RESULTS

Ninety-nine of 113 ESIR programs (87.6% response rate) reported a total of 176 approved ESIR positions. Based on this average of 1.78 positions per program, the actual number of ESIR positions in the U.S. is likely more than 200. While 111 fellowship programs in the U.S. currently offer a total of 331 positions, current new training pathways include 77 IntIR programs and 48 IndIR programs with 150 and 133 positions, respectively. As the Integrated IR programs matched at 100% in the same time frame, thus have no open positions, this leaves substantially more ESIR positions that must feed into Independent IR training programs than are currently available.

CONCLUSION

A substantial discrepancy currently exists with IR training pathways, as the number of available ESIR positions far outnumbers the available Independent IR pathway positions.

CLINICAL RELEVANCE/APPLICATION

Given that the Integrated IR Residency was the most competitive match in 2018 (100% of positions filled with more than 250 applicants not matching into IR), it is expected that the ESIR program will become increasingly utilized. However, if the number of ESIR positions far outnumbers the Independent IR residency positions, these trainees will be expecting to train in IR but may not find out until the end of their PGY-4 year (and after other specialties have matched) that they have no advanced training position.

SSE26-06 Fundamentals of Interventional Radiology Skills Training: The FIRST Curriculum

PURPOSE

There has been a paradigm shift in medical education, transitioning from an apprenticeship model to one centered on more directed skills training. There is a unique opportunity to embrace this changing landscape of medical education via usage of simulation-based training for interventional radiology. This is a preliminary study examining the efficacy of modules to be utilized in a forthcoming curriculum entitled, The Fundamentals of Interventional Radiology Skills Training (FIRST).

METHOD AND MATERIALS

A procedural checklist was generated from a core task analysis of two attendings performing each skill: venous access, biopsy, and interventional suturing. This checklist was then used to teach first year diagnostic radiology residents (n=7). A jugular venous access phantom was formed in realistic polycarbonate molds with a mixture of gelatin (7.4% by weight) and sugar-free psyllium fiber (4.6% by weight) combined with silicone tubing. This same gelatin and psyllium fiber mixture was also used for an ultrasound-guided liver biopsy phantom, with several targets at variable depths. Ultrasound (US) was performed with a portable GE VScan Dual Probe device. A high-fidelity suturing pad was also constructed from platinum-catalyzed silicone gels reinforced with power mesh. Pre- and post-session surveys utilizing a Likert scale were administered to quantify effectiveness of the teaching session with regard to (i) ability to perform skills and (ii) knowledge of procedural steps and equipment. Statistical analysis was performed using Mann-Whitney U Test.

RESULTS

On the pre-session survey, 100% of residents reported being uncomfortable with IR procedures. After the session, 100% of residents agreed simulation-based education would be invaluable prior to IR rotations. Compared to pre-session responses, there were significant differences in ability to perform a dermal stitch and drain knot ($p=0.0023$ for both), describe the steps in US-guided biopsy ($p<0.001$), and identify vascular access components ($p= 0.0017$).

CONCLUSION

These preliminary data demonstrate efficacy of dedicated IR skills teaching sessions and simulation using constructed phantoms. Our experience will inform future module development, including use of 3D printed vessels and a fluoroscopic trainer.

CLINICAL RELEVANCE/APPLICATION

A standardized simulation-based curriculum would be indespensible to IR trainee education to enable deliberate practice in a risk-free environment.

sdestounis@ewbc.com

PURPOSE

To review and compare performance of screening ultrasound in women with dense breast tissue post adoption of state breast density mandate.

METHOD AND MATERIALS

Through a retrospective chart review, data was collected on 23,878 screening ultrasound exams performed from 2013-2017 in patients with heterogeneously dense or extremely dense breast tissue. We stratified the data by year to compare screening ultrasound performance over time. Cancer detection rate (CDR), PPV and biopsy rate were calculated for US only findings (mammographically normal). Data was collected on patient demographics, number of DBT exams performed, BI-RADS score, pathology, tumor size, and lymph node status.

RESULTS

A total of 23,878 screening ultrasound exams were performed; 691 (2.9%) in 2013, 1700 (7.1%) in 2014, 4767 (20.0%) in 2015, 7389 (30.9%) in 2016, 9339 (39.1%) in 2017. Use of BI-RADS 1 and 2 remained stable; ranging from 95.0% in 2013 to 97.1% in 2017. The use of DBT increased in the population increased, from 18.7% in 2013 to 99.3% in 2017. Cancer detection rate increased in the first 3 years, from 1.4/1000 (2013) to 3.6/1000 (2015) then decreased in 2016 to 2.4/1000, and again in 2017 to 2.2/1000. Biopsy rate steadily decreased since 2013, from 2.9% to 1.0% in 2017. PPV for biopsy initially increased substantially (5% in 2013 to 20% in 2014) and then slightly declined; 18.8% in 2015, 16.2% in 2016, and increased again to 22.3% in 2017. The assignment of BIRADS 3 decreased over time; from 2.5% of exams in 2013, to .76% in 2017.

CONCLUSION

Screening ultrasound continues to detect mammographically occult malignancy, though the rate can vary substantially, as we saw an initial increase, followed by a decrease to 2.2/1000 in 2017. This decrease could be due to the increase in use of DBT, which increases the visibility of malignancies on mammography. The biopsy rate consistently decreased, from 2.9% to 1.0%, as did assignment of BI-RADS category 3. PPV varied over time, with the highest rate over the period in 2017 (22.3%), potentially suggesting more appropriate use of biopsy in this population.

CLINICAL RELEVANCE/APPLICATION

There are 30 states with breast density legislation. As policies continue to change and center around individualized medicine, understanding the performance and value of US will be helpful for facilities as they continue to adopt improved screening practices and modalities for women with dense breast tissue.

SSG01-02 Non-Mass Lesion Detected by Breast US: Stratification of Cancer Risk for Clinical Management

PURPOSE

To develop a practical diagnostic prediction model by using imaging features of breast non-mass lesion (NML) detected by B-mode ultrasonography (US).

METHOD AND MATERIALS

From Dec 2011 to March 2016, B-mode US was performed in 777 NMLs in consecutive 828 patients. This retrospective study consecutively included 669 breast NMLs in 669 patients for which final diagnoses were established and mammographies obtained at the time of US examination. For each lesion, radiologists assessed BI-RADS category. For developing a diagnostic prediction model to estimate malignant risk of NMLs using a scoring, univariate and multivariate logistic regression analyses were performed to find US or mammographic features associated with malignancy in a developmental dataset (n=460). A score for each significant imaging feature was assigned and multiplied by the regression coefficient, and the risk score of malignancy for each NML was defined as the sum of individual scores. Based on area under the receiver operating characteristic curve (AUC), diagnostic performance of the prediction model was compared to the radiologist's BI-RADS classification. Later, we verified the usefulness of developed scoring model by applying into the remaining validation dataset (n=209).

RESULTS

Among 669 NMLs, 354 (52.9%) were benign and 315 (47.1%) were malignant. In the developmental dataset, the following US features, within or around the main lesion, showed significant association with malignancy: the presence of calcifications, architectural distortion, posterior acoustic shadowing or abnormal ductal change, and absence of microcysts. The following mammographic features also showed significant association with malignancy: the presence of calcifications or focal asymmetry. The predictive model's AUC was higher than the radiologist's BI-RADS classification (0.952 vs. 0.930). In the validation dataset, AUC of our prediction model was 0.961.

CONCLUSION

The prediction model using features of US and mammography may be useful in stratification of cancer risk of breast non-mass lesions.

CLINICAL RELEVANCE/APPLICATION

Cancer risk stratification for breast non-mass lesions using features of US and mammography may be useful in managing breast non-mass lesions detected by US.

SSG01-03 Decreasing Short-Term Follow-Up and Biopsies by Following BI-RADS 3 Lesions at 1 Year: A Prospective Study

Tuesday, Nov. 27 10:50AM - 11:00AM Room: S406A

Participants
Richard G. Barr, MD, PhD, Campbell, OH (*Presenter*) Consultant, Siemens AG; Consultant, Koninklijke Philips NV; Research Grant, Siemens AG; Research Grant, SuperSonic Imagine; Speakers Bureau, Koninklijke Philips NV; Research Grant, Bracco Group; Speakers Bureau, Siemens AG; Consultant, Canon Medical Systems Corporation; Research Grant, Esaote SpA; Research Grant, BK Ultrasound; Research Grant, Hitachi, Ltd
Carmine Tinelli, MD, MSC, Pavia, Italy (*Abstract Co-Author*) Nothing to Disclose
Annalisa DeSilvestri, PhD, Pavia, Italy (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Supplemental US is know to detect node negative cancers not identified on screening mammography. However the large number of short-term follow-ups and low positive biopsy rate make this technique not cost effective. The majority of these are due to BI-RADS 3 lesions (B3), with an incidence of cancer in < 1%. This prospective study evaluates the effect of following B3 detected on supplemental ultrasound at 1 year.

METHOD AND MATERIALS

This HIPPA compliant, IRB approved with written informed consent study invited patients receiving a B1 or B2 screening mammogram with density 3 or 4 breast of any risk to receive a free automated volume whole breast (ABVS) ultrasound. The ABVS was performed on a Siemens S2000 using a 15cm L14-5 transducer. ABVS were read by radiologist with 20 year experience as BI-RADS category 1, 2, 3, or 0. Category 0 patients received a hand held ultrasound (HH). Patients were followed for 2 years.

RESULTS

Of 23426 screening patients, 8542(36.5%) had density 3 or 4 and were asked to participate. 2257 (26.4%) agreed to participate (50 yo mean age, range 31 to 90) (<10% high risk). The ABVS was interpreted as B1 in 1186 (52.5%), B2 in 591 (26.2%), B3 in 395 (17.5%) and B0 in 85 (3.8%). Of the 395 B3 patients, 310 had 1-year follow-up and were cancer free, 0%, 254 had 2-year follow-up and were cancer free, 0%. Of the 85 B0 patients, (recall rate of 3.8%) on HH 8 (11.3%) were B1, 51 (71.8%) were B2, 2 (2.8%) were B3, 6 (8.5%) were B4, and 4(5.6%) were B5. The B4 and 5 lesions were 2 B4A lesions were fibroadenomas,2 B4A were fibrocystic change, 2 category 4C lesions were IDC, and 4 category 5 lesions were IDC. The biopsy rate was 0.4% (10/2257) with a positive biopsy rate (PPV3) of 60.0% (6/10). The supplemental ultrasound detected 2.8/1000 additional cancers (4/1412). 5 cancers (0.28%, 5/1777) were detected in 3 yr f/u in B1 and B2 and 1 IDC (0.25%, 1/395) was identified in B3 in the contralateral breast.

CONCLUSION

Following B3 at 1 year interval decreases the recall rate (8.8% (233/2637) ACRIN 6666 to 3.8% (54/1412)) (p<0.001) and increases the PPV3 (8.9% (21/235)ACRIN 6666 to 60.0% (6/10))(p=0.001) without substantial node positive cancer misses. With these improved screening characteristic, supplemental ultrasound could be cost effective.

CLINICAL RELEVANCE/APPLICATION

Following B3 at 1 year markedly reduces the recall rate and increases the PPV3 making supplemental screening more cost effective.

SSG01-04 A Preliminary Study of Predicting Molecular Subtypes of Breast Cancer by the Radiomics Features of Contrast-Enhanced Ultrasound

Tuesday, Nov. 27 11:00AM - 11:10AM Room: S406A

Participants
Lei Tang, Shanghai, China (*Presenter*) Nothing to Disclose
Man Chen, Shanghai, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

The aim was to analyze the quantitative features of contrast-enhanced ultrasound(CEUS) imaging of breast cancer through computer image extraction, and to explore the preoperative prognosis of the different molecular subtypes of breast cancer.

METHOD AND MATERIALS

CEUS images of 189 patients were collected from our hospital. Everyone signed informed consent before CEUS. Surgical pathology and molecular typing results were obtained in all patients. Through mapping the borders of breast cancers on the images, the entire internal area of the tumor was determined. The lesions were divided into four quadrants(Fig 1). The high perfusion within the lesion area was defined as a high brightness area. The temporal and special features of the images in different areas were extracted by the computer in a dynamic CEUS file and the time intensity curves(TIC) were drawn. From the TIC curve, the features were extracted such as wash in rate(WiR), wash out rate(WoR), rise time(RT), base intensity(BI) and peak intensity(PI) and EI(=PI-BI), so on. The parameters of the curve in each area were calculated in different molecular typing groups.

RESULTS

The patient' numbers of Luminal A, Luminal B, HER2+, and triple negative breast cancer (TNBC) of each molecular subtypes were 46, 75, 37, and 31, respectively. The extracted effective features included EI of the internal bright area, WoR of internal bright area, WoR of the internal overall area, RT of the internal overall area, and so on. The cutoff value 1.566 of WoR in the internal bright area might help to find Luminal A, with a specificity of 82.61%. When to find TNBC, the cutoff value of EI at the internal bright area was 0.3494, the sensitivity was 64.52%, and the specificity was 68.99%. When distinguishing between Her2+ and TNBC, WOR of the internal overall had a cutoff of 5.7496 and a sensitivity of 74.19%.

CONCLUSION

The radiomics features of contrast-enhanced ultrasound could contribute to preoperative prediction of breast cancer molecular subtypes. Further research needed to be larger sample, multi-center expansion.

CLINICAL RELEVANCE/APPLICATION

The radiomics features of contrast-enhanced ultrasound could contribute to preoperative prediction of breast cancer molecular subtypes, which may help to predict efficacy and to select treatment options.

SSG01-05 Sonographic Features of Radial Scars and Complex Sclerosing Lesions

Tuesday, Nov. 27 11:10AM - 11:20AM Room: S406A

For information about this presentation, contact:

reni.butler@yale.edu

PURPOSE

To assess the morphologic characteristics of radial scars (RS) and complex sclerosing lesions (CSL) when they are visualized with ultrasound (US)

METHOD AND MATERIALS

A HIPAA-compliant, IRB-approved retrospective review of core needle biopsies (CNB) performed between 1/1/2007 and 12/31/2017 was performed and filtered for RS or CSL as the primary diagnosis. Patients with a concurrent diagnosis of malignancy or with only a microscopic incidental RS were excluded. The method of detection, mammographic and sonographic features, histology at CNB and at surgical excision, if performed, were recorded for all lesions visualized with US.

RESULTS

190 lesions with a CNB diagnosis of RS or CSL were identified. 57.4% (109/190) were visible on US. Most [75.2% (82/109)] US-visible lesions were initially detected on screening mammography, followed by screening US [19.3% (21/109)], diagnostic US [2.8% (3/109)], diagnostic mammography [1.8% (2/109)], and screening MRI [0.9% (1/109)]. Among US-visible lesions, 53.2% (58/109) appeared as non-mass areas of abnormal echogenicity, 44.0% (48/109) as masses, 1.8% (2/109) as architectural distortion only, and 0.9% (1/109) as dilated hypoechoic ducts. More lesions were anti-parallel [58.7% (64/109)] compared to parallel [41.3% (45/109)]. While most were hypoechoic [64.2% (70/109)], others were isoechoic [14.7% (16/109)], hyperechoic [3.7% (4/109)], or mixed [17.4% (19/109)]. Posterior acoustic features were most often none [58.7% (64/109)], followed by shadowing [28.4% (31/109)] and enhancement [12.8% (14/109)]. Color Doppler images, available in 87 lesions, showed no vascular flow in 34.5% (30/87), adjacent flow in 34.5% (30/87), and internal flow in 31.0% (27/87). Lesions presenting as architectural distortion on mammography [50.4% (55/109)] most often appeared as non-mass areas of variable echogenicity on US [89.1% (49/55)] rather than masses [10.9% (6/55)].

CONCLUSION

RS and CSL sonographic features are variable and include non-mass areas of abnormal echogenicity. While not strictly part of the BI-RADS lexicon, subtle 'nonmass' findings may be the only US correlate in some mammographically-detected lesions, especially those presenting as architectural distortion.

CLINICAL RELEVANCE/APPLICATION

As the incidence of RS and CSL increases with tomosynthesis utilization, understanding the variety of US appearances may increase the likelihood of detecting an US correlate and facilitate biopsy.

SSG01-06 Shear-Wave Elastography of the Breast: Value of a Novel 5-Point Technical Quality Score

Tuesday, Nov. 27 11:20AM - 11:30AM Room: S406A

Constance D. Lehman, MD,PhD, Boston, MA (*Abstract Co-Author*) Research Grant, General Electric Company; Medical Advisory Board, General Electric Company

For information about this presentation, contact:

mbaikpour@mgh.harvard.edu

PURPOSE

To determine the value of a novel 5-point technical quality score on the diagnostic performance of shear-wave elastography (SWE) of the breast.

METHOD AND MATERIALS

This IRB-approved HIPAA-compliant study included 110 consecutive women (mean age 55.1 + 15.3 years) with 122 breast lesions who underwent SWE and ultrasound-guided biopsy from Oct. 2017 to Jan. 2018. We recorded the maximum (Emax), mean (Emean), and standard deviation (Esd) elasticity measurements for each lesion. We defined five specific SWE technical quality parameters: (1) lesion visibility on B-mode image panel, (2) red pattern (high stiffness) in the near field of the field-of-view (FOV), (3) size and location of FOV box relative to lesion, (4) heterogeneity, vertical streaks, and absence of color in tissue surrounding the lesion, (5) size and location of the region-of-interest circle on the lesion for elasticity measurements. Three blinded readers independently assessed each SWE parameter as low (score=0) or high (score=1) quality. SWE total quality score < 3.3 was classified as low and > 3.3 as high. Intra-class correlation coefficient (ICC) was used to measure inter-observer agreement for the total score and the Hanley and McNeil's method was used to compare areas under the receiver operating characteristic curve (AUC) of SWE in low vs. high-quality images.

RESULTS

Mean size of the 122 lesions was 13.9 + 10.4 mm; 64 (52%) were benign and 58 (48%) were malignant. Inter-observer agreement was good among readers (ICC 0.805). AUCs were significantly improved in the high-quality group compared to the low-quality group for Emean (0.858 vs. 0.631, p=0.009; AUC difference=0.227, 95%CI [0.056, 0.398]) and Esd (0.816 vs. 0.629, p=0.040; AUC difference=0.187, 95%CI [0.008, 0.366]). AUC for Emax also increased to 0.861 in the high-quality group compared to 0.714 in the low-quality group but without statistical significance (p=0.077; AUC difference=0.147, 95%CI [-0.015, 0.309]).

CONCLUSION

Incorporating our novel 5-point technical quality score can improve the diagnostic performance of SWE in differentiating malignant from benign breast lesions.

CLINICAL RELEVANCE/APPLICATION

A simple 5-point technical quality metric provides guidance to users during real-time acquisition and improves diagnostic performance of SWE in differentiating malignant from benign breast lesions.

SSG01-08 Can Mid-Treatment Ultrasound in Triple Negative Breast Cancer Patients Predict Residual Pathologic Disease in the Axillary Nodes?

rcandelaria@mdanderson.org

PURPOSE

To determine if the number of abnormal lymph nodes visualized on mid-treatment ultrasound in triple negative breast cancer (TNBC) patients who are undergoing neoadjuvant chemotherapy associates with residual nodal disease on surgical pathology

METHOD AND MATERIALS

As part of an on-going single-institution, clinical trial of stage I-III TNBC patients, the first 106 patients who underwent surgery were included in this interim analysis. Mid-treatment was defined as the period following completion of four cycles of AC (Adriamycin and cyclophosphamide) chemotherapy and before initiating either anticipated Taxol chemotherapy or an investigational therapy. The number of abnormal nodes at mid-treatment was assessed and recorded by experienced, fellowship-trained breast radiologists. These radiologists empirically categorized lymph nodes using a binary approach of sonographically abnormal versus normal. Pathologic lymph node positive was defined as the presence of macrometastasis and micrometastasis in at least one axillary node from sentinel lymph node biopsy and/or axillary lymph node dissection as stated in the surgical pathology reports. Wilcoxon rank sum test and Fisher's exact test were used to determine statistical significance.

RESULTS

There were 26 of 106 patients (25%) who had residual nodal disease at surgery and 80 of 106 patients (75%) who had nodal pathologic complete response. The median number of abnormal nodes at mid-treatment was 3 (range 0-16 nodes) for patients who had residual nodal disease compared to 0 (range 0-12 nodes) for patients who had nodal pathologic complete response. TNBC patients with residual nodal disease on surgical pathology had significantly more abnormal nodes at mid-treatment ($p<0.0001$). More specifically, TNBC patients with at least 2 abnormal lymph nodes at mid-treatment ultrasound had a significantly higher chance of being pathologic lymph node positive at surgery ($p<0.0001$).

CONCLUSION

There is a highly significant association between the number of abnormal lymph nodes identified at mid-treatment ultrasound and the presence of residual metastatic axillary nodes at surgery in triple negative breast cancer patients.

CLINICAL RELEVANCE/APPLICATION

The number of abnormal lymph nodes at mid-treatment may be an independent predictor of residual disease in TNBC patients and may assist in identifying chemoresistant patients who could benefit from investigational therapies.

SSG01-09 Is a BI-RADS 4 or 5 Assessment Reasonable on Screening Ultrasound?

PURPOSE

For participants recalled for further testing, to determine the utility of a BI-RADS final assessment in determining management based on technologist-performed screening ultrasound.

METHOD AND MATERIALS

5689 women in three centers (1 academic and 2 private practice) were enrolled in an IRB-approved study of screening tomosynthesis (DBT) and technologist-performed handheld screening ultrasound (US, with orthogonal views of each finding other than simple cysts) and underwent 8151 screens (5689 yr1, 2462 yr2). Two experienced breast-imaging specialized radiologists prospectively reviewed each DBT-US set independently and in opposing order. Whenever additional imaging was recommended prior to the next annual screening, readers recorded a "final" assessment: BI-RADS 3, 4A, 4B, 4C or 5, together with recommendations, which could include immediate additional imaging and/or possible biopsy, or six-month follow-up. When US was read first and still resulted in a recall after integration with the DBT, we compared subsequent management and outcomes with the original BI-RADS assessments. We excluded technical recalls. At least targeted prior sonograms were available for 980 participants in year 1.

RESULTS

24 women were ultimately diagnosed with cancer after US recall, median patient age 55 (range 40-75). A total of 455 (5.6%) US exams prompted recall: 348/5689 (6.1%) in year 1 and 107/2462 (4.3%) in year 2. Of 209 women scored BI-RADS 3, 114 had immediate additional evaluation and 95 had 6-month follow-up; 20 (9.6%) ultimately had biopsy with 2 (1.0%) found to have cancer. Of 153 rated BI-RADS 4A on screening, 86 (56.2%) had biopsy and 2 (1.3%) proved malignant. Of 60 BI-RADS 4B, 40 (66.7%) had biopsy and 4 (6.7%) had cancer. Of 11 BI-RADS 4C, 11 (100%) had biopsy and 7 (63.6%) had cancer. Of 9 BI-RADS 5, 9 (100%) had biopsy and 9 (100%) were found to have cancer.

CONCLUSION

Malignancy and biopsy rates were lower than expected for a BI-RADS 4A or 4B assessment on technologist-performed screening US, but were reasonable for a BI-RADS 4C or 5 assessment.

CLINICAL RELEVANCE/APPLICATION

Directly scheduling biopsy based on screening US was appropriate for BI-RADS 4C and 5 assessments; 56% of 4A and 67% of 4B assessments resulted in biopsy after physician-targeted evaluation.

PURPOSE

The aim of this study was to investigate the prognostic value of coronary artery disease-reporting and data system (CAD-RADS) scores and determine the additional risk stratification benefit of CAD-RADS scores compared to coronary artery calcium score (CACS) and coronary artery disease (CAD) extent classifications in ischemic stroke patients without cardiac symptoms.

METHOD AND MATERIALS

From January 2013 to August 2014, 615 ischemic stroke patients who had at least one risk factor for CAD without chest pain underwent coronary computed tomography angiography (CCTA) and were included for final analysis. CT images were evaluated for CACS, extent of CAD and CAD-RADS scores. The primary endpoint was major adverse cardiovascular events (MACEs) defined as cardiovascular death, nonfatal myocardial infarction, unstable angina (UA) requiring hospitalization, revascularization and recurrent ischemic stroke event. Cox regression analyses were used to identify associations between CAD-RADS results and MACEs. C-statistics were calculated to compare discriminatory values of each model.

RESULTS

During the median follow-up period of 3.11 years, there were a total of 78 MACEs. Of 615 patients, 24.7% were classified as CAD-RADS 0, 19.3% as CAD-RADS 1, 17.6% as CAD-RADS 2, 18.5% as CAD-RADS 3, 15.6% as CAD-RADS 4A, 2.1% as CAD-RADS 4B, and 2.1% as CAD-RADS 5. CACS, CAD extent classification and CAD-RADS scores independently stratified risk of future MACEs (all $p < 0.05$). C-statistics revealed that both CAD extent classification and CAD-RADS scores improved risk stratification beyond CACS (C-index: 0.753 vs 0.698, $p < 0.001$ and 0.726 vs 0.698, $p = 0.041$, respectively).

CONCLUSION

In ischemic stroke patients without chest pain, CAD-RADS score had prognostic value for future MACE. In addition, CAD-RADS score provide additional risk-discrimination over CACS.

CLINICAL RELEVANCE/APPLICATION

CAD-RADS score provides additional risk-discrimination over CACS for the future major adverse cardiovascular events and can be recommended in the assessment of cardiovascular risk of stroke patient without chest pain.

SSG02-02 Machine Learning Outperforms CAD-RADS in Finding Optimal Prognostic Plaque Characteristics on Coronary CT Angiograms

PURPOSE

To use machine learning to find an optimal combination of coronary artery imaging features on CT angiography for the prediction of all cause mortality and coronary deaths, myocardial infarction and revascularization

METHOD AND MATERIALS

CT angiography was performed and risk factor data collected. Arteries were scored using CAD-RADS and 4 other published methods and compared to a score derived using machine learning. Causes of death were determined using the National Death Index. Myocardial infarction and revascularizations were discovered by follow-up letters. Prognostic results were compared using the area under the receiver operating characteristic curves.

RESULTS

7117 patients were imaged and followed for a mean of 9.0 years. There were 414 deaths from all causes, 79 attributed to coronary artery disease as the underlying or contributing cause, 51 myocardial infarctions (MI) and 231 revascularizations. The two best machine learning models were linear discriminant with diagonal covariance matrix and a classification neural network. Respective areas under the ROC curve were 0.76 and 0.77 for all cause mortality, 0.82 and 0.82 for coronary deaths or MI, and 0.87 and 0.88 for CHD or MI or revascularization. The corresponding CAD-RADS results were 0.71, 0.79 and 0.86.

CONCLUSION

Machine learning outperformed CAD-RADS for prediction of death and coronary events.

CLINICAL RELEVANCE/APPLICATION

Machine learning can be used to provide a prognostic score on coronary CT angiography that is comparable to or better than CAD-RADS.

SSG02-03 Development of a Deep Learning Algorithm for Predicting the Coronary Artery Calcium Score Using Retinal Images

PURPOSE

To determine if deep learning networks could be trained to estimate coronary artery calcium score (CACS) in heart CT scan from retinal images.

METHOD AND MATERIALS

All patients who obtained both ophthalmic examination and heart CT angiography at the tertiary center. Automated extraction of an OCT and retinal images was performed and linked to clinical end points from the electronic medical records. A deep neural network was trained to categorize images as either CACS<=10 (normal) or CACS>=100 (abnormal). We used the Modified VGG 11 model. We inserted one global average pooling layer instead of 2 fully-connected layers. To avoid overfitting, we had the data augmentation. At the SoftMax layer, the image that passed over the network was shown normal or abnormal binary probability value. Accuracy and Area under the receiver operating characteristic was estimated.

RESULTS

A total of 23,177 retinal images based on 15,056 examinations from 2,419 patients, who have received heart CT angiography including CACS, were extracted. At the examination level, we achieved an area under the ROC curve of 78.43% with an accuracy of 70%. At a patient level, we achieved an area under the ROC curve of 85.53% with an accuracy of 77.9%.

CONCLUSION

Using the non-invasive retinal examination including fundus photographs and OCT, deep learning networks show an impressive ability to predict the CACS, which is one of most important marker of heart disease.

CLINICAL RELEVANCE/APPLICATION

Deep-learning based screening of fundus photographs and OCT may have potential for a surrogate marker without radiation

exposure for high-risk patients with high coronary artery calcium score.

SSG02-04 Coronary Calcium Content Extracted by Machine Learning Methods from Incidental CT Scans Improves Coronary Heart Disease Prediction Accuracy

PURPOSE

Despite significant reductions in the last few decades, coronary heart disease (CHD) remains a significant cause of mortality. Many risk factors for CHD can be mitigated by lifestyle changes and pharmacological interventions, making risk calculation for individuals an important part of prevention. Accordingly, quantification of risk is integrated into prevailing management guidelines. Determination of coronary calcium content has been shown to allow improvement in risk calculation, but requires specialized tests that are not often performed. We present a novel algorithmic method that allows for the extraction of coronary calcium scores from incidental chest CTs performed for other indications, and demonstrate its utility in improving prediction accuracy over the American Heart Association (AHA) 2013 pooled risk model in a retrospective cohort study.

METHOD AND MATERIALS

There were 14,866 patients aged 30-74 with no prior CHD diagnosis included. CT scans and different covariates for the model were extracted in the two years prior to the index date (1 June 2012). Patients were followed-up for five years. Prediction performance results were compared between the AHA 2013 model (base model) and the same model with the novel coronary calcium score inserted as an additional predictor (augmented model). Both were logistic regression models and were trained on the sample population to allow comparison. For measures requiring a threshold, 3.5% risk over 5 years was chosen.

RESULTS

Based on the likelihood ratio test, the augmented model was superior to the base model (p-value <0.001). Similarly, the augmented model achieved superior performance for all performance measures: sensitivity increased 0.85%, specificity increased 4.9%, area under the ROC curve increased by 2.2% and there was a 4.5% categorical net reclassification improvement.

CONCLUSION

In this study, use of a novel biomarker extracted using a machine learning algorithm from incidental CT scans improves predictive accuracy compared to the commonly used model. This improvement occurs both in theoretical and practical measurements of model utility; in actual use it would translate into better clinical decisions.

CLINICAL RELEVANCE/APPLICATION

Coronary calcium content extracted via novel machine learning methods from incidental CTs significantly improves coronary heart disease prediction.

SSG02-05 Radiomics of Coronary Artery Calcium in the Framingham Heart Study

PURPOSE

To assess whether detailed coronary artery calcium (CAC) characterization based on radiomic feature extraction followed by machine learning improves prediction of cardiovascular (CV) events.

METHOD AND MATERIALS

Participants from the Offspring and third Generation cohorts of the community-based Framingham Heart Study who underwent chest CT between 2002 and 2005 were followed over a median of 9.1 years for cardiovascular events (CV) events (myocardial infarction, stroke, or death). Of those, 624 participants who had excellent image quality and CAC (Agatston score (AS)> 0) were randomly divided into discovery (n=318) and validation cohorts (n=306). CAC was segmented manually using 3DSlicer, and about 2000 radiomic features (based on intensity, shape, and texture of CAC) were extracted using pyRadiomics software. In the derivation cohort, we used an internal minimum redundancy maximum relevancy algorithm (without knowledge of events) to identify the 20 highest ranked features. Finally, a random forest classifier was used to optimize decision trees for prediction for CV events. The weighted predictive probabilty of events for each of the 20 features was summarized into a radiomic score. The performance of this score was tested independent in the validation cohort.

RESULTS

The discovery (66.1% men, 58.1±11.1 age) and validation cohorts (61.4% men, 59.3±11.2 age) had similar CV risk profile, median AS, and CV event rates (30/318 =9.7% and 29/306=9.5%, respectively). In adjusted multivariate analysis (for Framingham risk factors and AS), participants in the validation cohort, who had radiomic scores in the mid and upper tertiles had significantly higher risk for events as compared to the lower tertile (mid: HR= 9.3, p=0.03, upper: HR=16.5, p=0.007). The area under the curve (AUC) was higher for AS, radiomic score (RS), and combined AS/RS were 0.73, 0.76 and 0.79; respectively in the overall population. Performance was best in the subgroup with AS <300 (n=250, Figure)

CONCLUSION

This proof-of-concept study demonstrates that detailed CAC characterization based on radiomic feature extraction predicts CV events independent of traditional risk factors and AS. Further validation is necessary to determine clinical impact.

CLINICAL RELEVANCE/APPLICATION

Artificial intelligence may identify a prognostically important radiomic signature of CAC.

PURPOSE

Several invasive and radionuclide imaging markers of coronary plaque vulnerability have been described. Identification of these imaging biomarkers by a single, widely available non-invasive technique may provide an opportunity to identify vulnerable plaques and vulnerable patients in daily clinical practice. Therefore, our aim was to assess the diagnostic accuracy of coronary computed tomography angiography (CTA) derived radiomic features to identify attenuated plaque using intravascular ultrasound (IVUS), thin-cap fibroatheroma per optical coherence tomography and radionucleide uptake using sodium fluoride positron emission tomography morphologic (NaF18-PET) as compared to conventional qualitative and quantitative CT metrics.

METHOD AND MATERIALS

We analyzed 44 plaques in 25 patients using IVUS, OCT, NaF18-PET and coronary CTA. We assessed 7 conventional qualitative and quantitative plaque characteristics and calculated 935 radiomic parameters. We calculated receiver operating characteristics area under the curve (AUC) values using a 5-fold cross validation with 1000 repeats to assess diagnostic accuracy. We used the Kolmogorov-Smirnov test to compare the distribution of AUC values resulting from the cross-validations.

RESULTS

Radiomics outperformed conventional metrics to identify attenuated plaque per intravascular ultrasound, thin-cap fibroatheroma by optical coherence tomography and metabolically active plaques per sodium fluoride positron emission tomography in CT images (AUC: 0.72 vs 0.59; 0.80vs 0.66; 0.87 vs 0.65; p<0.001 all; respectively).

CONCLUSION

Computed tomography radiomics may allow the non-invasive identification of invasive and radionuclide imaging biomarkers.

CLINICAL RELEVANCE/APPLICATION

Radiomics is able to identify morphologic and metabolic high-risk plaque features currently olny identifiable using invasive and radionucleide imaging, which are both important components of plaque instability.

SSG02-07 Epicardial Fat is Increased in the HIV Population and Associated to Coronary Artery Plaque Burden

PURPOSE

HIV patients are exposed to a higher risk of coronary artery disease (CAD) compared to non-infected patients. The exact mechanism responsible for this increased risk is not well understood. HIV individuals are also exposed to changes in body fat distribution characterized by greater ectopic fat. These changes may play a role in promoting atherosclerosis. Epicardial fat, which is the ectopic fat related to the heart, may play a unique role because of its location near to the coronary arteries. We hypothesize that epicardial fat volume is increased in the HIV patients and correlates with total coronary plaque volume, and with low attenuation plaque volume, which is a marker of plaque vulnerability.

METHOD AND MATERIALS

This is a cross sectional study, nested in the Canadian HIV and Aging Cohort Study (CHACS), a large prospective cohort following more than 800 HIV+ and HIV- patients. Consecutive CHACS participants with low to intermediate cardiovascular risk without symptoms or past CAD were invited to undergo cardiac computed tomography (CT) and coronary plaque imaging with CT angiography. Volume measurement of epicardial fat, total atherosclerotic plaque and low-attenuation plaque were performed. Association between epicardial fat volume, coronary plaque volume and low attenuation plaque volume was assessed using multivariate linear regression.

RESULTS

A total of 246 participants underwent cardiac CT scans. 173 were HIV+ and 73 were HIV-. HIV+ patients had greater epicardial fat volume indexed to body mass index (BMI) than HIV- patients ($p = 0.03$). In the HIV infected group, epicardial fat volume was associated with duration of antiretroviral therapy use ($ß = 1.45$, $p = 0.004$). After adjustment for traditional cardiovascular risk factors, BMI and waist circumference, epicardial fat volume was significantly associated with total plaque volume ($ß = 1.99$, $p = 0.04$) and low attenuation plaque volume ($ß = 0.86$, $p = 0.01$).

CONCLUSION

Epicardial fat volume is increased in the HIV participants . The association of epicardial fat volume with antiretroviral therapy duration and subclinical coronary artery plaque may suggest a potential mechanism that could explain the increased risk for CAD in the HIV population.

CLINICAL RELEVANCE/APPLICATION

Epicardial fat is increased in HIV patients and correlates with total coronary plaque volume and low attenuation plaque volume, a CT marker of plaque vulnerability.

SSG02-08 Subclinical Coronary Atherosclerosis among Individuals with HIV on Antiretroviral Therapy

PURPOSE

To compare coronary plaque burden and characteristics between HIV-infected and non-HIV-infected participants

METHOD AND MATERIALS

This cross-sectional study nested in a large prospective cohort was approved by the local Institutional Review Board. All subjects provided written consent. Consecutive HIV+ and HIV- participants were prospectively recruited for cardiac computed tomography (CT). Eligibility criteria were males/females, no known coronary artery disease, low/intermediate 10-yr Framingham risk score (FRS, 5-20%), no CT contraindication. Coronary calcium scoring was done with non-contrast CT, and contrast-enhanced CT for plaque (calcified vs noncalcified, volume) and lumen assessment. Imaging assessors were blinded to HIV status. Analyses used multivariate multiple linear and logistic regression models.

RESULTS

A total of 246 participants (173 HIV+ (93% males), 73 HIV- (81 % males)) were included, with similar age (mean 55 yo, p=0.69) and FRS (median 11 %, p=0.53). Diabetes (10% vs 1.4 %, p=0.01) and smoking (28% vs 14 %, p=0.02) were more frequent in HIV+ than HIV- participants, and elevated LDL cholesterol less frequent in HIV+ participants (20% vs 32%, p=0.07). Median duration of HIV infection in HIV+ participants was 18 yrs. All were on antiretroviral therapy (median 15 yrs). After adjusting for diabetes, smoking and LDL cholesterol, prevalence and plaque extent was similar between HIV+ and HIV- participants (72 % vs 69 %, p= 0.37; 2.9 ± 3.0 vs 2.7 ± 3.8 plaques/participant, p= 0.53). HIV+ participants showed more frequent noncalcified and less frequent calcified plaques than HIV- participants (0.3 ± 0.7 vs 0.1 ± 0.5, p=0.01; 1.4 ± 2.4 vs 2.0 ± 2.0 plaques/participants, p=0.006). Number of mixed plaques (1.0 ± 1.4 vs 0.6 ± 1.4 plaques/participant, p= 0.27), mean calcium score (148 vs 141, p=0.81), plaque volume (273 vs 218 mm3, p=0.91) and prevalence of >= 70% stenosis (10% vs 6%, p=0.40) were similar between HIV+ and HIV- participants.

CONCLUSION

Noncalcified plaques are more frequent in asymptomatic HIV+ individuals under antiretroviral therapy, while calcified plaques are less frequent, in comparison to HIV- individuals, after adjustment of cardiovascular risk factors.

CLINICAL RELEVANCE/APPLICATION

Noncalcified plaques are usually considered more vulnerable plaques. Our findings suggest one anatomic substrate that could explain the increased risk of myocardial infarction in the HIV population.

SSG02-09 Atherosclerosis of Coronary Arteries in HIV Patients on Routine Non-Gated CT Chest: Incidence, Characteristics, and Risk Factors

Tuesday, Nov. 27 11:50AM - 12:00PM Room: S104B

Participants
Mayil S. Krishnam, MBBS, MRCP, Orange, CA (*Presenter*) Nothing to Disclose
Edgar Karanjah, MBChB, Orange, CA (*Abstract Co-Author*) Nothing to Disclose
Eduardo Hernandez-Rangel, MD, Monterrey, Mexico (*Abstract Co-Author*) Nothing to Disclose
Eun Jin Chae, MD, PhD, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the incidence and risk factors of subclinical coronary artery calcification (CAC) in patients with Human Immunodeficiency Virus (HIV) infection.

METHOD AND MATERIALS

We retrospectively reviewed 143 HIV patients (M:F = 119:24; mean age, 46.4) who underwent routine non-gated CT of thorax, from May 2010 to November 2015. Each of the four main coronary arteries was identified-left main stem (LMS), left anterior descending (LAD), left circumflex (LCX), and right coronary artery (RCA)- on CT images. Calcification in each artery was categorized as absent, mild, moderate, or severe by a radiologist. A multivariate logistic regression was performed to find independent risk factors for positive CAC. Clinical and laboratory parameters reflecting the status of HIV infection, including CD4 count, viral load, duration since HIV diagnosis, and status of antiretroviral treatment.

RESULTS

Forty-one patients (28.7%) showed calcifications in one or more coronary arteries. LAD (n=38, 92.7%) was most commonly affected, followed by LCX (n=18, 43.9%) and RCA (n=13, 31.7%). CAC deposited at the proximal portion in LAD and LCX (76.3%, 77.7%, respectively) while at the mid to distal portion in RCA (61.5%). Age of CAC+ group (53.9 years) was significantly higher than that (43.4 years) of CAC- group (p < 0.001). Minimum age of HIV patient with positive CAC was 24yrs. Duration of HIV infection in CAC+ group (12.3 years) was significantly higher than that (8.6 years) in CAC- group (p<0.0344). The mean viral load was significantly lower value in CAC+ group compared to that in CAC- group (76K versus 414K, p=0.02). CAC+ group showed significantly higher CD4 cell counts than CAC- group (mean=355.9 versus 175.3, p= 0.0053). There was no significant difference in HAART status between the two groups (current HAART receivers 84.4% versus 85.7%, p=0.539). On multivariate logistic regression, age, HIV duration, and CD4 were significantly associated with CAC+ (p-values<.05)

CONCLUSION

Patients with HIV showed early onset and increased incidence of CAC and associated with higher CD4 cell counts. Duration of HIV is an independent risk factor for coronary artery calcification, in addition to age of patients.

CLINICAL RELEVANCE/APPLICATION

Awareness of increased risk of atherosclerosis development in young-age HIV-infected patients is crucial for primary prevention of future cardiovascular events.

PURPOSE

To evaluate the added value of a deep-learning based computer-aided detection (CAD) system for multiclass multiple lesions on radiographs when radiologists read chest radiographs.

METHOD AND MATERIALS

We developed new CAD system using deep learning for detecting multiple lesions with 4 different patterns (nodule/mass, interstitial opacity, pleural effusion, and pneumothorax) on chest radiograph. To train the deep learning network, 17917 images were collected in two tertiary hospitals. Numbers of normal and abnormal patients are 11000 and 6917, respectively. We labeled disease type and delineate region of interests (ROI) drawn as ground truths by two thoracic radiologists with consensus. To validate the effect of the developed CAD on observer's performance, 9 observers including 7 board-certified radiologists and two radiology residents reviewed 200 chest radiographs twice with two weeks interval. 200 chest radiographs consists of 100 normal and 100 abnormal (nodule/mass: 60, interstitial opacity: 10, pleural effusion: 10, pneumothorax: 10) chest radiographs. The diagnostic performance of the developed CAD, observers with and without CAD were evaluated and compared using jackknife free-response receiver operating characteristic (JAFROC) figure of merits (FOMs) on a per-lesion basis. The reading time for review was recorded.

RESULTS

The developed CAD showed FOMs of 0.931 for nodule/mass, 0.900 for interstitial opacity, 1 for pleural effusion, and 1 for pneumothorax. The mean FOMs of 9 observers without CAD were 0.916 for nodule/mass, 0.922 for interstitial opacity, 0.944 for pleural effusion, and 0.978 for pneumothorax. After applying the CAD, the mean FOMs of 9 observers were 0.942 for nodule/mass, 0.900 for interstitial opacity, 0.967 for pleural effusion, and 1 for pneumothorax. Except for interstitial opacity, the accuracy of three patterns with CAD increased. The mean reading time was 91.5 minutes ± 53.2 without CAD and 79.1 minutes ± 28.2 with CAD.

CONCLUSION

The deep-learning based CAD may help improve observer performance for reading chest radiograph as well as reducing reading time.

CLINICAL RELEVANCE/APPLICATION

The deep-learning based CAD has the potential to improve observer efficiency in terms of accuracy and reading and may provide preliminary interpretation for chest radiographs.

SSG03-02 A Retrospective, Multi-Center Clinical Study for Validating Increased Lesion Detection Accuracy of Radiologists When Using Computer-Aided Detection System in Reading Digital Chest X-Ray Images

PURPOSE

To evaluate performance of radiologists detecting pulmonary malignant nodules assisted by deep-learning based computer-aided detection (CAD) software, compared with performance of radiologist or CAD alone.

METHOD AND MATERIALS

Each of four participating centers in three countries retrospectively collected 150 lung cancer radiographs and 50 normal radiographs. Normal x-ray images are from healthy adults, confirmed by a CT scan taken within 14 days. Each cancer x-ray image has 1 to 3 pathologically confirmed nodule(s), whose sizes are between 1 and 3 centimeters. The estimated location of each nodule was marked on x-ray image referring to the CT scan. 12 radiologists from 4 institutions with various experiences independently analyzed a set of x-ray images and marked region of interests (ROIs) on each radiograph in suspicion of a nodule. Deep learning-based computer-aided detection (CAD) software was applied to find suspicious nodules on chest radiographs. Finally, 12 radiologists reviewed whole set of images with assistance of CAD, accepting or dismissing ROIs suggested by CAD. Sensitivity and false negative per image (FPPI) of radiologist alone, CAD alone and radiologist with CAD were statistically analyzed.

RESULTS

The overall sensitivity and FPPI of the CAD system were 63.75% and 0.20, which was not statistically distinct from those of radiologists. The average sensitivity of radiologists appeared to increase significantly from 65.1% to 70.3%, after aided by the CAD software ($p<0.0001$). The average FPPI was 0.2 and 0.18, without and with CAD, respectively. The decline of FPPI was significant ($p=0.0006$). On subgroup analysis, incremental effects of CAD on nodule detection sensitivity were not affected by radiologists' experience, size, location, type (primary or metastatic) of nodules and modality of acquisition.

CONCLUSION

The average sensitivity and FPPI of our CAD system were not statically different from those of radiologists. When radiologists were assisted by the CAD, overall sensitivity increased significantly while FPPI seemed to decrease. Incremental effect of the CAD system was not affected by radiologist's experience, characteristics of a nodule or modality, which can support the potential general use of this software.

CLINICAL RELEVANCE/APPLICATION

Radiologists' performance in lung cancer nodule detection can be improved with a deep learning-based CAD system regarding both sensitivity and false positive rate.

SSG03-03 Nodule Size Measurement: Automatic or Human-Which is Better for Predicting Lung Cancer in a Brock Model?

PURPOSE

To assess the impact of automated segmentation of pulmonary nodules by measuring the accuracy of the prediction of malignancy

using the Brock University Cancer Prediction Model.

METHOD AND MATERIALS

Retrospective analysis was carried out of 7927 nodules (of which 314 were malignant) from 5394 patients who were scanned as part of the US NLST (mean age 62±5 years; of which 3192 were male). Following BTS guidelines, nodules <5mm in size were excluded, but all other nodules were included regardless of type, attenuation, and margin. Automatic 3D nodule segmentations were generated via a deep learned model and initiated with a single click point inside the nodule. We used the following methods for measuring nodule size: the NSLT radiologist measurements, D2D, the long axis from the automatic segmentations, D3D, and in order to characterize the nodule volumes more accurately, the volumes of the automatic segmentations, V, were converted to an equivalent linear size using the equation for a sphere. Each was tested as the size term in the standard Brock model to generate a malignancy risk and Area-Under-the-Receiver-Operating-Characteristics (AUC-ROC) curve calculated.

RESULTS

The AUC-ROC was 85.96% (95% confidence interval (CI): 84.33, 87.76) for D2D, 86.64 (95% CI: 85.04, 88.19) for D3D, and 88.17 (95% CI: 86.71, 89.82) for Dsph. The expected increase in AUC Dsph offers over D2D is 2.21 (95% CI: 1.28, 3.12).

CONCLUSION

The automatic nodule size measurements outperformed the manual radiologist measurements in predicting lung cancer as an input to the Brock model. The non-axial Dsph, which is derived from the volumetric segmentation outperforms both long axis-based methods. Assessing nodule segmentation by measuring prediction efficacy is a viable alternative to overlap measures such as DICE.

CLINICAL RELEVANCE/APPLICATION

Automatic segmentation removes the need for manual extraction of axial diameters of lung nodules. It is not subject to intra- and inter-radiologist variation thereby improving consistency.

SSG03-04 Effect of Artificial Intelligence Based Vessel Suppression and Automatic Detection of Part-Solid and Ground-Glass Nodules on Low-Dose Chest CT

PURPOSE

Most studies with CAD and artificial intelligence (AI) software have focused on solid lung nodules. We assessed the effect of AI-based vessel suppression (AI-VS) and automatic detection (AI-AD) on ground glass (GGN) and part-solid lung nodules (PSN) in low-dose CT (LDCT).

METHOD AND MATERIALS

Our study included 100 LDCT examinations with mixed attenuation pulmonary nodules (average diameter>5mm) identified from the National Lung Cancer Screening Trial (NLST). These exams were not used in training or validation of the AI software (ClearRead CT, Riverain Inc.). All 100 LDCT were processed to generate three image series per case - unprocessed, AI-VS, and AI-AD series with annotated lung nodules. Two thoracic radiologists (R1: 3-year experience, R2: 27-year experience) independently assessed the unprocessed images alone, then together with AI-VS series, and finally with AI-AD. For each assessment, number of all > 5mm with location & size of dominant GGN and PSN were recorded. Descriptive statistics and student t tests were performed for data analysis.

RESULTS

On unprocessed images, R1 and R2 detected 278 nodules (123 PSN, 155 GGN) and 269 (117 PSN, 152 GGN), respectively (p>0.05). With addition of AI-VS images, R1 and R2 detected 290 nodules (126 PSN, 164 SSN) and 293 (132 PSN, 161 GGN), respectively, which were significantly greater than those detected without the AI-VS (p= 0.004). AI-VS aided in detection of solid component in 22 PSN which were deemed SSN by both readers. Conversely, AI-AD annotated only 75 PSN and 54 GGN (total 129 nodules). In 21 patients, AI-AD did not detect the dominant PSN or SSN; it detected 14 false positive nodules (vessels, atelectasis, anterior junctional line). Average respective sizes of 69-matched and detected PSN on unprocessed and AI-AD series were 15 ±7 mm and 13 ± 6 mm (p =0.07).

CONCLUSION

AI-VS improves detection and characterization of GGN and PSN on LDCT of the chest. Specifically, improved and easier detection of the solid component in non-solid nodules with AI-VS can avoid false down-grading of Lung-RADS category, and thus help in appropriate patient management.

CLINICAL RELEVANCE/APPLICATION

AI software can aid in improved detection and confident detection of ground-glass and part-solid lung nodules on low dose chest CT.

SSG03-05 Evaluation of Lung Nodules with FDG PET-CT: The Value of MIP Reconstructions in Conventional Thoracic CT Images During Shallow Breathing versus Images in Deep Inspiration

Tuesday, Nov. 27 11:10AM - 11:20AM Room: S504AB

montserrat.alemany.ripoll@akademiska.se

PURPOSE

Detection of small lung nodules is important for apropiate staging of cancer. There is controversy in literature about the value of adding a separate CT of the lungs in deep inspiration. Radiation dose is no longer an issue with the use of modern equipment because only aproximately 3 mSv are added to the usual dose. The purpose of this study was to assess the value of additional thoracic CT in deep inspiration and the use of maximum intensity projection (MIP) reconstructions in PET-CT of oncologic patients.

METHOD AND MATERIALS

186 consecutive patients (99 male and 89 female; mean age,72 years; range: 26-93 y) underwent FDG PET-CT for one of the following indications: characterization of a new detected lung nodule/mass (n=101), staging of cancer (n=31), therapy respons monitoring (n=33), suspicion of tumor relapse (n=19) and cancer of unknown origin (n=2). After PET-CT acquisition with shallow breathing, a thoracic CT in deep inspiration was performed to all patients (slide thickness: 1.25 mm). MIP of the two sets of lung images were performed. Two experienced radiologist analyzed the 4 sets of CT studies. The number of lung nodules was recorded. Lung nodule was defined as a rounded opacity smaller than 10 mm completely surrounded by lung parenchyma. The clinical relevance of the eventual discrepancies between CT studies was analized (i.e. upstaging).

RESULTS

120/186 patients presented with nodules. PET-CT with shallow breathing detected 393 nodules, and 578 when MIP images were analized. Thoracic CT with deep inspiration found 534 nodules and 905 when MIP was used. The number of detected nodules increased from free breathing to breathe hold CT in 42 patients. The detected number of nodules with breath hold technique compared with free breathing increased increased in 51 patients when MIP was used. The extradetected nodules were considered clinical relevant in 7/120 (6%) of patients because they influence patient management for example by increasing TNM staging.

CONCLUSION

According to our results the addition of deep inspiration thoracic CT with MIP reconstructions can be recommended in clinical practice because this approach yields better performance in TNM staging in oncologic patients.

CLINICAL RELEVANCE/APPLICATION

Addition of deep inspiration CT with MIP reconstructions to conventional FDG PET-CT in oncologic patients yields better performance in TNM staging.

SSG03-06 Deep Learning for Rule-Out of Unnecessary Follow-Up in Patients with Incidentally Detected, Indeterminate Pulmonary Nodules: Results on an Independent Dataset

PURPOSE

To assess the follow-up rule-out accuracy of a convolutional neural network (CNN) in patients with incidentally detected, indeterminate pulmonary nodules in a multi-site, heterogeneous population.

METHOD AND MATERIALS

The US National Lung Screening Trial (NLST) dataset was manually curated and used to create a training set: each reported nodule and cancer was located, contoured and diagnostically characterised (9310 benign nodule patients; 1058 cancer patients). All patients with solid and semi-solid nodules of 6mm and above, where benign nodules and cancers could be confidently identified by clinicians (5972 patients, of which 575 were cancer patients), were selected. A CNN was trained using Deep Learning and three thresholds for benign rule-out were calculated at three levels of sensitivity: 100%, 99.5% and 99%. An independent dataset of patients with incidentally detected indeterminate pulmonary nodules was retrospectively collected from a tertiary referral centre and surrounding hospitals in the UK with a heterogeneous mix of scan parameters, manufacturers and clinical indications (610 patients, 698 nodules, 5-15mm). Diagnosis was established according to British Thoracic Society guidelines (2015). The dataset contained 50 cancers from 47 patients (7% of all nodules). Performance was evaluated by measuring the specificity at the three benign rule-out thresholds; i.e. to measure the proportion of benign nodules correctly stratified while missing no or few cancers. Overall Area-Under-the-ROC-Curve analysis (AUC) was also calculated.

RESULTS

The specificity (sensitivity) was 24% (100%), 24% (100%) and 48.6% (100%) at the three thresholds respectively. AUC was 0.93 (95%CI = 0.90-0.96).

CONCLUSION

On this independent dataset, the CNN was able to correctly classify just under half of the benign nodules whilst not misclassifying any cancers.

CLINICAL RELEVANCE/APPLICATION

Our work shows the potential of CNNs in ruling out benign pulmonary nodules and therefore reducing the need for follow up scans in a large number of patients.

SSG03-07 A Decision Analysis of Follow-Up and Treatment Algorithms for Subsolid Pulmonary Nodules

markmhammer@gmail.com

PURPOSE

To use simulation modeling based on evidence from the literature to evaluate several management strategies and treatment options for patients with ground glass nodules (GGNs).

METHOD AND MATERIALS

We developed a Monte Carlo model for patients with GGNs as they underwent follow-up per Lung-RADS for up to ten years. Nodules could grow and develop solid components over time. Rates of clinically-significant malignancy were calibrated to data from the National Lung Cancer Screening Trial. We investigated modifications to the follow-up schedule and tested different treatment strategies, specifically lobectomy, radiation therapy, and no therapy.

RESULTS

Overall, 2.3% of nodules represented clinically significant malignancies, and 6.3% of nodules were treated. Only 29.8% of Lung-RADS 4B/4X nodules were clinically-significant malignancies. We compared outcomes of patients with Lung-RADS 2 nodules followed at 1-, 2-, and 3-year intervals; overall survival at 10 years of follow-up was similar, ranging from 74.7% (annual) to 73.5% (triennial). We also evaluated 10-year outcomes from Lung-RADS 4B/4X non-solid nodules treated with different modalities; at 10 years, overall survival was highest in the radiation therapy arm, at 83.9%, and lowest in the no treatment arm, at 78.1%.

CONCLUSION

Our results suggest a conservative approach to the follow-up and treatment of GGNs. The follow-up interval for GGNs can be increased to 3 years with minimal change in outcomes. Our results also favor the use of radiation therapy when a nodule has met criteria for treatment. Prospective randomized trials are needed to evaluate thresholds for management and different treatment modalities for GGNs.

CLINICAL RELEVANCE/APPLICATION

Conservative management strategies for non-solid nodules, such as triennial follow-up for Lung-RADS 2 nodules and radiation therapy instead of lobectomy for Lung-RADS 4B/4X nodules, are preferable to more aggressive treatment.

SSG03-08 A Robust Model for Prediction of Pulmonary Nodule Malignancy with CT Scans

PURPOSE

Pulmonary nodules could be early manifestations of lung cancer, but the morphological complexity makes it difficult to differentiate benign and malignant nodules. This paper proposes two deep learning models aiming to accurately determine the malignancy of pulmonary nodules from CT images.

METHOD AND MATERIALS

Model-1 was adapted from the winning model in Data Science Bowl 2017.. We chose ResNet as its backbone and integrated U-Net and Capsule Network architectures to enable the model to comprehensively capture multiscale features of pulmonary nodules. Model-2 took extracted features from Model-1 as input to a random forest classifier to further predict nodule malignancy, as inspired from the NoduleX model. Two datasets were adopted to validate the performance of the proposed two models. Dataset 1 contains 1061 samples (benign/malignant: 703/353) from Lung Image Database Consortium and Image Database Resource Initiative (LIDC-IDRI), and Dataset 2 consists of 1117 samples (benign/malignant: 354/763) provided by collaborating hospitals. Nodules in both datasets were biopsy or surgery proven, and pathology diagnoses were used as gold standard. We randomly selected 20% from each dataset as the testing set and used the rest 80% as the training set. We trained and tested our two models on the above two datasets respectively.

RESULTS

On Dataset 1 (LIDC-IDRI), Model-1 achieved an AUC of 0.91 in the prediction of pulmonary nodule malignancy while Model-2 achieved an AUC of 0.96. On Dataset 2, Model-1 again reached a high AUC of 0.90, which significantly outperformed the Model-2 with AUC=0.80.

CONCLUSION

Model-1 showed consistently high accuracy in pulmonary nodule malignancy prediction on both the LIDC dataset and CT scans collected from collaborating hospitals. Our two models achieved comparable results with NoduleX model which had got the state-of-the-art performance in LIDC dataset. The experimental results demonstrated that Model-1 showed more stable performance across datasets and had better model robustness. The strength of Model-1 may lie in its Capsule Network structure that could extract more universally informative features and the end-to-end deep learning architecture.

CLINICAL RELEVANCE/APPLICATION

Our proposed model can serve as a useful tool for early diagnosis of lung cancer and has the potential to be applied in clinical treatment planning.

SSG03-09 External Validation of the McWilliams Model to Predict Probability of Cancer in Pulmonary Nodules using NLST Data

Tuesday, Nov. 27 11:50AM - 12:00PM Room: S504AB

PURPOSE

Lung cancer screening results in the discovery of an estimated 1.57 million screen- and incidentally-detected pulmonary nodules. Prediction models, which estimates the probability of lung cancer in pulmonary nodules detected on computed tomography (CT) can potentially aid in manage patients and minimize overdiagnosis. Thus, we performed an external validation of an existing model developed by McWilliams et al (doi:10.1056/NEJMoa1214726).

METHOD AND MATERIALS

Based on the inclusion/exclusion criteria stated by McWilliams, we identified 7,879 non-calcified nodules greater than 4 mm discovered at the baseline CT screening with at least 2 years of follow-up using data from the CT arm of the National Lung Screening Trial (NLST). We assessed model discrimination (the ability to distinguish between cancer/not cancer) and calibration (the agreement between predicted and observed probabilities). We identified differences between PanCan, the derivation dataset, and NLST. The regression coefficient and the intercept coefficient were estimated by fitting a logistic regression on NLST. We also attempted to update and recalibrate the model. Finally, we evaluated whether the addition of new covariates such as body mass index, smoking status, pack-years and asbestos improved performance.

RESULTS

While the AUC of the model was good 0.905 [0.882-0.928]), the histogram plot showed that whether a nodule was cancer/not cancer could not be well-separate (see Figure, left). The calibration plot showed that the model tended to overestimate the probability of cancer. Following methods in Steyerberg et al (doi: 10.1002/sim.1844), the updated model achieved an AUC of 0.914 [0.892-0.936] and a better calibration (see Figure, right). Emphysema ($p=0.03$) and nodule spiculation ($p<0.01$) had a significantly different effect in the NLST cohort compared to the PanCan. Among the new covariates, only the pack-year history was found to be significant ($p<0.01$).

CONCLUSION

While the model achieved high AUC, discrimination and calibration remain suboptimal, motivating our efforts to improve additional clinical, imaging, and the evolution of covariates over time that could influence performance.

CLINICAL RELEVANCE/APPLICATION

External validation is necessary to assess generalizability of a prediction model to new patients. We show how discrimination and

External validation is necessary to assess generalizability of a prediction model to new patients. We show how discrimination and calibration can be examined to assess how models can likely enter in clinical practice.

falessandrino@bwh.harvard.edu

PURPOSE

The purpose of our study was to describe and categorize diagnostic errors in cervical spine CT interpretation (CsCT) performed for trauma and to assess their clinical significance.

METHOD AND MATERIALS

All CsCT studies with diagnostic errors that came to our attention based on clinical or imaging follow up from 2004 to 2017 were analyzed. Errors were categorized as extraspinal or spinal, osseous or soft tissue finding, according to anatomical site and level for each spinal finding. All images were reviewed by a musculoskeletal fellowship trained emergency radiologist and a spine surgeon. For each error, the spine surgeon assessed the need for 1) surgery, 2) immobilization and 3) MRI. Findings were considered clinically significant if the answer to any of the three questions was positive.

RESULTS

56 patients with CsCTs and reports containing diagnostic errors were reviewed. 12 patients (21.5%) had missed or misinterpreted finding in extraspinal location. 44 patients (78.5%) had errors localized to spine (28 fractures/dislocations, 15 intervertebral disc protrusions, 1 lytic bone lesion). The locations of missed/misinterpreted fractures were: transverse (n=8), spinous process (n=6), facet (n=4), lamina (n=2), vertebral body (n=11), C1 (n=3), occipital bone (n=1). Two dislocations were at the atlantoaxial articulation (n=2). 4 patients had missed fractures encompassing more than one anatomical location. The most common spinal fracture levels were C5 (n=7) and C7 (n=6). In 4 patients, additional contiguous (n=2) or noncontiguous (n=2) fractures were missed. Responses to the three questions were positive in 3, 25, and 16 patients, respectively. All fractures were considered clinically significant, including 3 patients who would have required surgical stabilization (2 atlantoaxial dislocations and 1 facet fracture). None of the intervertebral disc protrusions were reported to alter the management by the surgeon.

CONCLUSION

65.9% of our patients in our series with diagnostic errors localized to spine on CsCTs were considered clinically significant, potentially altering therapeutic and diagnostic management. Transverse process fractures were the most common clinically significant missed/misinterpreted finding.

CLINICAL RELEVANCE/APPLICATION

Radiologists should be aware of commonly missed injuries on CsCT and their clinical significance so they can adjust their search pattern and improve the accuracy of their reports.

SSG04-02 Diagnostic Value of Prevertebral Soft Tissue Thickening on Cervical Spine CT in Acute Trauma, Using MRI as the Reference Standard

Tuesday, Nov. 27 10:40AM - 10:50AM Room: S403A

Participants
James S. Kho, MBBCh, Brighton, United Kingdom (*Presenter*) Nothing to Disclose
Ahmed Daghir, MRCP, FRCR, Oxford, United Kingdom (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

james.kho@bsuh.nhs.uk

PURPOSE

Population normal values of prevertebral soft tissue (PVST) thickness on CT have been established but there is little previously published research examining whether an abnormal PVST thickness on CT has diagnostic value as a sign of cervical spine injury. This study aims to evaluate whether an abnormal PVST on CT is a predictor of anterior column soft tissue injury on cervical spine MRI.

METHOD AND MATERIALS

The radiology information system(RIS) at a tertiary trauma centre was searched for Emergency Department patients over 18 years of age who had a CT of the cervical spine for trauma from 1st January 2017 onwards, which was followed by a cervical spine MRI within 7 days. Exclusion criteria include previous spinal surgery and intubated patients. 40 consecutive patients meeting inclusion and exclusion criteria were selected. For each CT study, PVST thickness on CT at levels C1 to C7 were measured, and the PVST thickness was categorised as normal or abnormal based on previously published normal values by Rojas et al in 2009. The corresponding MRI images and reports were reviewed for anterior column soft tissue injury (prevertebral haematoma or anterior longitudinal ligament injury). The performance of abnormal PVST thickness on CT as a predictor of MRI findings of anterior column soft tissue injury was evaluated and diagnostic odds ratio, sensitivity and specificity were calculated.

RESULTS

Prevertebral soft tissue thickening on CT is strongly associated with findings of anterior column soft tissue injury on MRI ($p = 0.0002$), with a diagnostic odds ratio of 32.7, specificity of 93% and sensitivity of 70%.

CONCLUSION

Prevertebral soft tissue thickness should be evaluated on cervical spine CTs as it is a useful radiological sign of anterior column soft tissue injury.

CLINICAL RELEVANCE/APPLICATION

When reporting cervical spine CTs, anterior column soft tissue injury should be strongly suspected if there is prevertebral soft tissue thickening.

SSG04-03 Spinal Trauma in DISH: Is MRI Essential After the Detection of Vertebral Fractures on CT?

Tuesday, Nov. 27 10:50AM - 11:00AM Room: S403A

Awards
Student Travel Stipend Award

Bharti Khurana, MD, Boston, MA (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

nshah@bwh.harvard.edu

PURPOSE

1. To assess the incidence of posterior column involvement on CT and MRI in patients with diffuse idiopathic skeletal hyperostosis (DISH) and known anterior/middle column injury on CT. 2. To evaluate the utility of performing MRI in DISH patients with isolated anterior/middle column fractures and no neurological deficit.

METHOD AND MATERIALS

Records of 177 consecutive patients older than 50 years of age admitted between 2008 and 2017 for a traumatic spinal fracture and a diagnosis of DISH were reviewed. Only fractures involving an ankylosed region of the spine were included. Patients with fractures involving a non-ankylosed spine segment and history of prior spine surgery were excluded. Age, gender, mechanism of trauma, fracture type, spine CT and MRI imaging findings, surgical intervention, neurologic deficit, complications, and in-hospital mortality were collected from the medical records.

RESULTS

26% (47/177) of patients had hyperextension injuries; overall, 59% (106/177) had either non-displaced or minimally displaced fractures. 116/177 (66%) patients had fractures isolated to the anterior/middle column. 22/177 patients had fractures isolated to the posterior column only and 39/117 patients had fractures involving both the anterior/middle and posterior columns. 97 patients in our cohort underwent MRI after a fracture was detected on CT. 75 of the 97 patients had fractures isolated to the anterior/middle column. Of these 75, 26 had disruption of the posterior ligamentous complex (PLC), and only 4 of the 26 patients had no neurologic deficit. 28 of the 97 patients had either spinal cord injury or epidural hematoma and 27/28 of these patients presented with neurological deficit. The one patient that did not present with neurologic deficit had a tiny dorsal epidural hematoma without spinal

cord injury or disruption of the PLC and was managed conservatively.

CONCLUSION

1. 49% of patients in our cohort (87/177) had either a posterior column fracture on CT or disruption of the PLC on MRI. 2. In DISH patients with isolated anterior/middle column fractures and no neurologic deficit, MRI did not provide additional information that would change management in most cases (85%).

CLINICAL RELEVANCE/APPLICATION

In most DISH patients with anterior/middle column fractures only and no neurologic deficit, spine CT alone is sufficient for management without the additional time and money spent on MRI.

SSG04-04 Incidence and Patterns of Cervical Spine Injuries on CT: A Study in a Level I Trauma Center

Tuesday, Nov. 27 11:00AM - 11:10AM Room: S403A

Participants
Shekhar Khanpara, MD, Houston, TX (*Abstract Co-Author*) Nothing to Disclose
Daniel Ruiz-Pardo, MS, Bogota, Colombia (*Abstract Co-Author*) Nothing to Disclose
Susanna C. Spence, MD, Houston, TX (*Abstract Co-Author*) Nothing to Disclose
O. C. West, MD, Houston, TX (*Abstract Co-Author*) Royalties, Reed Elsevier
Roy Riascos, MD, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

Though spinal fractures constitute a minority of all trauma, the financial burden imposed is very significant especially cervical spine trauma. The pattern of cervical spine injuries in the setting of trauma in general population is unknown at the moment in United States with very few papers addressing the issue. We reviewed entire spectrum of cervical spine injuries and demonstrated correlation between various demographics, clinical presentation with radiological appearance of the injury.

METHOD AND MATERIALS

We performed retrospective analysis of 13,500 patients who underwent imaging for cervical spine trauma at a level I trauma center. Out of this database we selected 934 patients who had a positive CT scan. Each patient was then analyzed by reviewing the medical records and correlation was sought between demographic, clinical and imaging features.

RESULTS

In our study, the peak incidence of cervical spine trauma was in the age group of 21-30 years followed by 31-40 years with a male:female ratio of 2.1. Major cause of injury in the study population was motor vehicle accidents (66.1%), followed by fall from height of less than 8 feet (12.2%). For fractures of vertebral bodies, we identified 440 injury levels, with C1 and C2 being the most frequent fractured as compared to the subaxial spine. Incidence of C2 fractures (40.9%) was higher as compared to C1 (23.2%). Body and lateral mass fracture incidence was marginally higher as compared to odontoid fractures. C7 (11.3%) was the most fractured vertebral body in the subaxial spine followed by C6 (8%) and C5. Highest number of vertebral body fractures were due to compression injury. 924 injury levels were identified for vertebral body process with transverse process fractures (38.6%) being the most common.

CONCLUSION

Spinal trauma is on the rise and it helps to understand the frequency and pattern of injuries in cervical spine to guide us for better management of these patients.

CLINICAL RELEVANCE/APPLICATION

To understand the distribution and pattern of injuries in cervical spine on a plain CT in the setting of trauma to improve delivery of healthcare.

SSG04-05 The Combination of SWI and DTI in Evaluating the Severity of Traumatic Brain Injury

Tuesday, Nov. 27 11:10AM - 11:20AM Room: S403A

Participants
Chengru Song, Zhengzhou, China (*Presenter*) Nothing to Disclose
Jingliang Cheng, MD,PhD, Zhengzhou, China (*Abstract Co-Author*) Nothing to Disclose
Yong Zhang, DO, Zhengzhou, China (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

songchengru@126.com

PURPOSE

To explore the diagnostic value of SWI and DTI on different severity's traumatic brain injury(TBI).

METHOD AND MATERIALS

Totally 60 TBI patients (including 20 mild TBI patients, 20 moderate TBI patients and 20 severe TBI patients) and 20 health volunteer underwent SWI, DTI and conventional MRI examination. The numbers of involving regions, numbers and areas of

hemorrhagic lesions detected by SWI, and FA values of 37 brain regions (including knee, body, splenium of corpus callosum, cingulate bundle, et al.) were compared between each two groups. The correlation analysis between GCS scores and the number of involving regions, number of hemorrhagic lesions, areas of hemorrhagic lesions detected by SWI, and FA values of each region were performed.

RESULTS

The differences of involving regions' number, lesions' number, lesion's areas detected by SWI between each two groups were statistically significant (P<0.05). Severe TBI group got the maximum number of involving regions, lesions, and the largest areas. Followed by moderate group and mild group. Among the 37 regions, totally 30 regions differ in FA values between the four groups (P<0.05). And among these 30 regions, 18 regions' FA values, for example corpus callosum region, gradually reduce as the severity of TBI aggravate. The GCS scores are highly negatively correlated with the number of involving regions, number of lesions, areas of lesions detected by SWI, but are positively correlated with 30 regions' FA values. The descending order of relevance is hemorrhagic lesions' areas(r=-0.932), lesions' number(r=-0.911), involving regions' number(r=-0.900), FA values of right cingulum(r=0.872), right anterior limb of internal capsule(r=0.801), left cingulum (r=0.787), the splenium of corpus callosum(r=0.775), the body of corpus callosum (r=0.765), et al.

CONCLUSION

The clinical applications of SWI and DTI is valuable in diagnosing different severity's TBI.

CLINICAL RELEVANCE/APPLICATION

SWI and DTI are effective in evaluating the severity of traumatic brain injury

SSG04-06 Iodine Maps on Follow-Up DECT: Prognostic Value in Patients with Cerebral Hemorrhagic Contusions in Moderate to Severe Head Trauma

Tuesday, Nov. 27 11:20AM - 11:30AM Room: S403A

ubodanapally@umm.edu

PURPOSE

We aimed to retrospectively determine if the quantitative data derived from Iodine Maps of follow-up head DECT can predict the 6-month mortality and unfavorable outcome scores in patients with cerebral contusions as derived from IMPACT model.

METHOD AND MATERIALS

This study was HIPAA compliant and institutional review board approved. Informed consent was waived. We retrospectively analyzed admission and 6-hour follow-up CT studies in 69 patients with hemorrhagic contusion(s). We incorporated the previously described powerful conventional CT outcome predictors related to the dominant lesion and new variables derived from Iodine Maps in our evaluation. After performing univariate analysis, the independent predictors were determined by using regression analysis.

RESULTS

CT variables with significance on univariate analysis were, hematoma volume at admission (Spearman's rho=0.38, p=0.03 for mortality; Spearman's rho=0.36, p=0.04 for unfavorable outcome), hematoma volume on follow-up (Spearman's rho=0.42, p=0.001 for mortality; Spearman's rho=0.38, p=0.004 for unfavorable outcome), enhancing penumbra volume (Spearman's rho=0.47, p=0.0003 for mortality; Spearman's rho=0.43, p=0.001 for unfavorable outcome), iodine concentration (Spearman's rho=0.32, p=0.02 for mortality; Spearman's rho=0.3, p=0.03 for unfavorable outcome), iodine content in penumbra (Spearman's rho=0.5, p=0.0002 for mortality; Spearman's rho=0.45, p=0.001 for unfavorable outcome), iodine content in contusion (Spearman's rho=0.5, p = 0.0002 for mortality; Spearman's rho=0.44, p=0.001 for unfavorable outcome). There was no correlation between the fractional hemorrhagic progression of contusion (%HPC) and the outcomes. Enhancing penumbra volume, and iodine content in penumbra were the independent predictors of both the outcome scores on regression analysis (B=10.9, p=0.002; B=9.22, p=0.02 for mortality; B=13.1, p=0.003; B=11.4, p=0.02 for unfavorable outcome).

CONCLUSION

Enhancing penumbra volume, and iodine content in penumbra may be more accurate for predicting outcomes in patients with cerebral contusions, than the previously identified predictor variables of hematoma volumes and %HPC.

CLINICAL RELEVANCE/APPLICATION

Quantitative iodine based CT variables derived from extravasated iodine into the contusions may improve the accuracy of the existing prediction models.

SSG04-07 Supplementing Screening Criteria Yields Increased BCVI Incidence, with Subsequent Imaging Showing Markedly Increased Risk for Ischemic Stroke

Tuesday, Nov. 27 11:30AM - 11:40AM Room: S403A

Participants
Frank Bensch, MD, PhD, Helsinki, Finland (*Presenter*) Nothing to Disclose
Elina Varjonen, MD, Helsinki, Finland (*Abstract Co-Author*) Nothing to Disclose
Seppo K. Koskinen, MD, PhD, Stockholm, Sweden (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Blunt cerebrovascular injuries (BCVI) are uncommon, but can have severe consequences such as ischemic stroke. Detection of BCVI requires an angiogram of the cervical arteries, commonly by CT angiography (CTA). CTA screening criteria for BCVI based on clinical findings and trauma mechanism have improved detection. Denver criteria for screening are most commonly used in absence of a clear consensus. Since clinical findings are often inconclusive, many patients do not meet any of these criteria. The aim of this study was to analyze the effect of augmented Denver criteria on BCVI incidence, as well as to determine the relative risk for ischemic stroke.

METHOD AND MATERIALS

For a single level one trauma center, Denver screening criteria for BCVI were augmented by including any high-energy trauma, cervical spine fracture, and major chest injury. All acute blunt trauma WBCT studies over a period of 38 months were reviewed retrospectively for distribution and grade of BCVI by two board-certified radiologists blinded to initial results. Non-CTA studies were excluded and any disagreements settled by consensus. Any subsequent cerebral imaging studies were reviewed for ischemic lesions appearing at a later phase.

RESULTS

1544 WBCT studies included 374 CTA (m/f=271/103; mean age 41.5 years). Most common mechanisms of injury were MVA (51.5%) and fall from a height (22.3%). We found 72 BCVI in 56 patients (15.0%), with 13 (23.2%) multiple lesions. The internal carotid artery (ICA) was affected in 49 (68.1%) and the vertebral artery (VA) in 23 (31.9%) of cases. Most common injury grades were Biffl I and II in both ICA and VA, with C2 as the most common level. Gender (p=0.1482) and age (p=0.611) had no impact on BCVI incidence. Interobserver agreement was substantial (Kappa=0.674). Subsequent imaging of 215 patients revealed cerebral ischemic stroke in 19.6% of BCVI and 3.5% of the remaining cases. Fisher's exact test shows this difference to be highly significant (p<.0001) with an OR of 9.77 (95% CI; 3.3-28.7).

CONCLUSION

Augmenting Denver screening criteria yielded an almost threefold incidence for BCVI in blunt trauma than expected (15.0%), which emphasizes the need for more liberal screening protocols. The markedly elevated relative risk for ischemic stroke following BCVI with an OR of 9.77 underlines the urgency of this proposal.

CLINICAL RELEVANCE/APPLICATION

Supplementing screening criteria for BCVI might markedly improve patient outcome.

SSG04-08 Frequency of Acute Findings in Head CT Scans Performed in the Emergency Department

Tuesday, Nov. 27 11:40AM - 11:50AM Room: S403A

Participants
Evgeni Druskin, Ramat Gan, Israel (*Presenter*) Nothing to Disclose
Dafna Nesselroth, Tel Aviv, Israel (*Abstract Co-Author*) Nothing to Disclose

Eyal Zimlichman, Ramat Gan, Israel (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Head CT is the most common CT scan conducted in the ED. The aims of this study were to evaluate the frequency of acute findings on head CTs conducted in the ED in different age groups, and to analyze head CT referral indications.

METHOD AND MATERIALS

Institutional review board (IRB) approval was granted for this study. Informed consent was waived by the IRB committee. The records of one tertiary care hospital's ED were retrospectively reviewed for consecutive adult patients who underwent head CT during a time frame of 40 days from January 1st 2017. CT interpretations were obtained and checked for demographics, referral indications and CT findings. Findings were divided into three groups: Acute findings, chronic findings and normal head CT. The cohort was divided into groups according to age: young adults (aged 19-40), adults (aged 41-65) and elderly (over 65 years old). Associations between referral indications and acute findings were calculated.

RESULTS

During the study's time frame, 12,958 adult patients presented to our ED. 1,621 of them (12.5%) underwent a head CT (young adults 221/1621=14.4%, adults 404/1,621= 26.3%, and elderly 913/1,621=59.4%). Acute findings were found in 15% of the patients and the frequency increased with age (young adults 12.2%, adults 13.6%, elderly 17.2%, p=0.027). Chronic findings were found in 24% of the patients (young adults 5.9%, adults 18.3%, elderly 30.6%, p<0.001). The distribution of acute findings for the entire cohort was: brain hemorrhage 32.6%, brain infarct 27.6%, SOL 23.0%, fractures 8.4%, sinusitis 11.3% and hydrocephalus 9.2%. Brain hemorrhage was the most common finding in young adults (29.2%) and in the elderly (36.3%), while SOL was the most common in the adult group (36.4%). The top three referral indications were neurological signs (19.7%), trauma (15.6%) and headache (12.3%). Headache was the most common indication in young adults (25.1%) and neurological signs were the most common in the adults and elderly groups (20.6%, 20.0%, respectively). Seizures were associated with acute findings (p=0.024, OR=1.917) and dizziness with absence of acute findings (p=0.022, OR=0.528).

CONCLUSION

Acute findings are found in 15% of head CT scans performed in the ED. The frequency of acute and chronic findings increases with age.

CLINICAL RELEVANCE/APPLICATION

The increasing amount of head CTs and the relatively low yield of this test, requires the implementation of decision protocols.

SSG04-09 Evaluation of the Big-5 CT-Protocol: Diagnostic of Ischemic Stroke Including Origins

Tuesday, Nov. 27 11:50AM - 12:00PM Room: S403A

Participants

Ulf K. Teichgraeber, MD, Jena, Germany (*Abstract Co-Author*) Research Consultant, W. L. Gore & Associates, Inc Research Consultant, Siemens AG Research Consultant, CeloNova BioSciences, Inc Research Consultant, General Electric Company

PURPOSE

Approximately 20-40% of ischemic strokes are caused by a cardio genetic embolic disease. Evidence of the embolic origin cannot become clearly defined. The goal of this study was the implementation of an extended stroke protocol (Big-5, see Fig. 1) for evaluation of thrombo-embolic sources, detection of pulmonary artery embolism, carotid artery stenosis and acute aortic syndrome in one initial exam.

METHOD AND MATERIALS

Imaging was performed using a high-end CT in the ER (Revolution CT, GE Healthcare). All patients (n=208) received an unenhanced brain scan for hemorrhage exclusion. Subsequently a combined ECG-gated/non-ECG-gated scan (caudo-cranial) for the assessment of heart, aortic arch, carotid arteries and brain vessels. Consecutively 40 s after CM injection another ECG-gated acquisition in diastolic phase covering the left atrial appendage and left atrium. Finally, a dynamic neuro perfusion scan was performed. All patients had no contraindication for CM or any known iodine allergy. Image quality of left atrium appendage was scaled with a 5-tier Likert-scale by 2 radiologists.

RESULTS

Excluded were 48 patients due to external causes (motion artifacts, IC, etc.). In 60/160 patients a pathological finding, in 54 (34%) patients morphological change consistent with acute stroke was detected. Cardiogenic thrombus sources could be found in 8/160 cases, 6 in the left atrial appendage and 2 on the aortic valve. One type A aortic dissection was documented. In 3/54 patients with acute stroke a cardiac source of thrombus, in 18 cases a severe stenosis or occlusion of carotid vessels and in 20 cases extensive thrombotic plaques of aortic arch or carotids and in 13 patients an intracranial arterial thrombus could be found. Image quality of left atrium appendage was significantly better in venous phase compared with CTA arterial phase (141 vs. 107 cases as good or very good, $p<0.001$).

CONCLUSION

Big5 provides extensional clinical information for patients with acute ischemic stroke compared to the traditional CT stroke examination protocol.

CLINICAL RELEVANCE/APPLICATION

Concomitant pathologies including pulmonary artery embolism, carotid artery stenosis and acute aortic syndrome could make the initial clinical assessment difficult and can be excluded. There is higher prevalence of pathologic findings in carotid vessels than in detection of intracardial thrombus.

PURPOSE

We compare reproducibility (CoV) of the Apparent Diffusion Coefficient (ADC) histogram for a standard Diffusion Weighted Imging (DWI) protocol against methods that correct for respiratory motion artifact and account for tumour volume, in order to assess the feasability of such methods to improve sensitivity of ADC in a multicentre setting.

METHOD AND MATERIALS

Data was acquired from 2 different 1.5 Tesla (T) vendors located at 3 centres. Test and retest images were acquired within 7 days. Two DWI acquisition protocols were used, A (standard) and B (allows for retrospective motion correction). Protocol B data was motion corrected using a previously published retrospective method. Similarly, a previously published model that estimates tumor volume related statistical error was applied (defined as S). The suitability of the model to describe this data set distribution was tested using Chi-squared ($\chi 2$) goodness of fit. Histogram analysis of reproducibility was calculated with a 5% level of significance for each method, A, B and S. The within-patient coefficient of variance (CoV) compared ADC reproducibility between methods for all the chosen histogram metrics (mean, median, 5th, 20th, 95th percentiles). Upper 95% limits of agreement (LoA) were calculated to define thresholds for detecting a statistically significant percentage change in ADC (ΔADC%).

RESULTS

15 patients (5 per site) were scanned. Although an improvement in sensitivity (CoV) was observed after motion correction (4.4% (A) vs. 3.2% (B) for mean ADC), no significant improvement was observed for the ADC histogram. Correcting for tumour size (S) in motion corrected data (B) significantly ($p<0.05$) improved CoV estimates (1.5% for mean ADC). The 95% LoA for ΔADC% narrowed from 12.7% (A) to 8.9% (B) to 1.9% (S). Sensitivity for the 20th percentile improved the most (20% to 2.4% 95% LoA)

CONCLUSION

This study demonstrates the feasibility of applying methods to improve ADC histogram sensitivity in a multicentre setting. Accounting for tumour volume and motion artifact improves estimates of reproducibility to within 1.5% (CoV for mean ADC),The 20th percentile demonstrated the largest improvement in sensitivity.

CLINICAL RELEVANCE/APPLICATION

Considering statistical error related to individual tumour volumes, and correcting for motion artifact, improves the sensitivity of the ADC to detect a significant post treatment response, in patients with colorectal liver metastases.

SSG05-02 Impact of Gadoxetate-Disodium vs. Gadoterate-Meglumine on Quantitative Respiratory and Hemodynamic Metrics Viewed through the Lens of a Compressed-Sensed MR Imaging Sequence

Tuesday, Nov. 27 10:40AM - 10:50AM Room: S503AB

Participants
Carl Glessgen, MD, Basel, Switzerland (*Presenter*) Nothing to Disclose
Manuela Moor, Basel, Switzerland (*Abstract Co-Author*) Nothing to Disclose
Bram Stieltjes, MD,PhD, Basel, Switzerland (*Abstract Co-Author*) Nothing to Disclose
Tobias Heye, MD, Basel , Switzerland (*Abstract Co-Author*) Nothing to Disclose
Daniel Boll, Basel, Switzerland (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To primarily test whether any contrast administration leads to respiratory irregularities. Secondarily, to quantify respiratory anomalies during the injection cycle comparing gadoxetate with gadoterate meglumine, and to assess whether utilization of free-breathing acquisition schemes using compressed sensing, parallel imaging and golden-angle radial sampling (GRASP) may yield additional quantitative information helpful in correcting imaging anomalies through respiratory gating.

METHOD AND MATERIALS

This prospective, IRB approved study examined a population of 497 patients; 338 received gadoxetate, 159 received gadoterate. All underwent GRASP imaging (TR/TE=4/2ms,ST=3.5, 0.56x0.56cm, temporal resolution=10s). Consecutive acquisitions during 250sec allowed dynamic imaging; each imaging was initiated 20 seconds prior to injection. Quantitative assessment evaluated (1)aortic enhancement (ROI in abdominal aorta), (2)respiratory translation of liver (ROI in liver dome) and (3)K-space based detection of plethysmographic excursion of diaphragm. (1)allows determination of individual contrast phases and hemodynamic metrics. (2)enables quantification of respiratory dynamics through changes in hepatic intensity; (3) enables extraction of plethysmographic signal strength curves and calculation of individual respiratory parameters.

RESULTS

Hemodynamic metrics did not differ between the 2 administered contrast agents ($p>0.05$). Both agents showed a mean signal drop of the hepatic ROI, with significantly higher (-52,3%vs-37,2%, $p=0.003$) and steeper (-.0211vs-.0165 ; $p< 0.001$) values for gadoxetate. Patients receiving gadoxetate had decreased breathing amplitude during entire examination (0.37 vs. 0.43, $p<0.001$), and specifically during pre-bolus and early arterial phases (0.32 vs. 0.42, $p = 0.018$). Enabling intrinsically inherent respiratory gating led to no significant differences in hepatic translation between the 2 patient populations.

CONCLUSION

Injection of any type of contrast agent potentially leads to respiratory irregularities with differing intensities and time point of maximum occurrence. Intrinsically enabled respiratory gating through the GRASP methodology compensated for any respiratory irregularities.

CLINICAL RELEVANCE/APPLICATION

Gadoxetate is an essential diagnostic tool for hepatobiliary phase MR imaging, GRASP methodology allows to compensate for any respiratory irregularities.

SSG05-03 Modified CAIPIRINHA-VIBE Without View-Sharing: Excellent Sequence to Detect HCC Without Motion Artifact on Multi-Arterial Gadoxetic Acid-Enhanced Liver MRI

Tuesday, Nov. 27 10:50AM - 11:00AM Room: S503AB

cinematiclife7@hanmail.net

PURPOSE

To evaluate the diagnostic performance of the modified CAIPIRINHA-VIBE without view-sharing and compare it with the CAIPIRINHA-DIXON-TWIST-VIBE with view-sharing on multi-arterial gadoxetic acid-enhanced MRI in the assessment of HCC

METHOD AND MATERIALS

We retrospectively identified 65pathologically confirmed hepatic tumors(<=3cm) in 65patients(51men,14women;mean age,60.9years) with cirrhosis or chronic hepatitis who underwent multi-arterial gadoxetic acid-enhanced MRI between June 2016 and March 2018.All patients underwent triple-arterial-phase imaging using the modified CAIPIRINA-VIBE without view-sharing(n=33)or the CAIPIRINHA-DIXON-TWIST-VIBE with view-sharing(n=32).We analyzed images to compare the diagnostic performance of two sequences for HCC, with categorization by LIRAD.We assessed the motion artifacts at triple-arterial phase of two sequences.The diagnostic performance for HCC and the incidence of motion artifacts were compared between two sequences using Fisher's exact test.

RESULTS

Among 65 patients, 33patients with 33pathologic proven liver nodules(28HCCs,3cholangiocarcinomas,1cHCC-CC and 1FNH) underwent triple-arterial-phase image using modified CAIPIRINA-VIBE without view-sharing,and remaining 32 patients with

32pathologic proven nodules(27HCCs, 4cholangiocarcinomas, and 1adenoma) underwent triple-arterial-phase image using CAIPIRINHA-DIXON-TWIST-VIBE with view-sharing.The sensitivity for detecting arterial enhancement in HCC was significantly improved in the group using the modified CAIPIRINA-VIBE without view-sharing(96.4%;95% C.I.,76.39 to 99.9),compared to the group using CAIPIRINHA-DIXON-TWIST-VIBE with view-sharing(74.7%; 95% C.I.,47.7 to 91.8)(p=0.025).Detection of motion artifact in triple-arterial-phase was significantly decreased in the group using modified CAIPIRINA-VIBE without view-sharing(2/33), compared to the group using CAIPIRINHA-DIXON-TWIST-VIBE with view-sharing(9/32)(p=0.023)

CONCLUSION

The modified CAIPIRINA-VIBE without view-sharing can improve the diagnostic performance of multi-arterial-phase of gadoxetic acid-enhanced MRI in the evaluation of HCC without motion artifact, compared to CAIPIRINHA-DIXON-TWIST-VIBE with view-sharing.

CLINICAL RELEVANCE/APPLICATION

Multi-arterial phase using modified CAIPIRINA-VIBE without view-sharing can overcome motion artifacts in multi-arterial phase using CAIPIRINHA-DIXON-TWIST-VIBE with view-sharing, resulting in provide optimal arterial phase imaging.

SSG05-04 Quantification of Hepatic Steatosis and Iron Overload at 3.0 Tesla: Comparison of Qualitative T1 Two-Point DIXON and Quantitative T2* Corrected Multi-Echo DIXON with MR Spectroscopy as the Reference Standard

Tuesday, Nov. 27 11:00AM - 11:10AM Room: S503AB

Awards
Student Travel Stipend Award

Participants
Chenyang Zhan, MD, New York, NY (*Presenter*) Nothing to Disclose
Tiejun Zhao, PhD, Pittsburgh, PA (*Abstract Co-Author*) Employee, Siemens AG
Sonja Olsen, New York, NY (*Abstract Co-Author*) Nothing to Disclose
Hersh Chandarana, MD, New York, NY (*Abstract Co-Author*) Equipment support, Siemens AG; Software support, Siemens AG; Advisory Board, Siemens AG; Speaker, Bayer AG;
Hoi Cheung Zhang, New York, NY (*Abstract Co-Author*) Nothing to Disclose
Krishna Prasad Shanbhogue, MD, New York, NY (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To compare the qualitative 3D T1 VIBE two-point Dixon technique (First look Dixon) with Inline Liver Segmentation and quantitative T1 independent T2* corrected volumetric multiecho Dixon proton density fat fraction (PDFF) using HISTO (STEAM spectroscopy sequence) as a reference for evaluation of liver fat and iron content at 3.0 T.

METHOD AND MATERIALS

Retrospective, HIPAA compliant, IRB approved study included 435 patients with known or suspected liver disease. Two-point DIXON, multi-echo DIXON and MR spectroscopy (HISTO) sequences were performed for each patient at 3.0 Tesla.The two-point DIXON sequence qualitatively assigned each patient to one of four categories: 'normal', 'fat', 'iron', 'fat and iron deposition'. A cut off of 5% fat fraction on multi-echo DIXON and HISTO was used to differentiate presence or absence of hepatic steatosis. The results of two-point DIXON and multi-echo DIXON were compared using HISTO as the reference standard.For iron overload, qualitative results from Two-point DIXON were compared with multi-echo DIXON using R2* cutoff values of 70 sec-1 for minimal iron overload and 110 sec-1 for mild iron overload.

RESULTS

PDFF using multi-echo DIXON showed sensitivity of 0.80, specificity of 0.85, with PPV of 0.83, and NPV of 0.83. This technique failed in 18 patients (4.1%) due to fat/water swap. The two-point DIXON technique showed sensitivity of 0.97 and specificity of 0.56, PPV of 0.65, and NPV of 0.95 for presence of hepatic steatosis. Two point DIXON had 0% failure rate.The percentage of patients qualitatively classified as 'iron deposition' by two-point DIXON is 28% among patients with R2* value greater than 70 ms-1, and 75% among patients with R2* value greater than 110 ms-1.

CONCLUSION

Compared with quantitative PDFF from multi-echo DIXON, qualitative fat evaluation from two-point DIXON was more sensitive but less specific for detection of hepatic steatosis. Two-point DIXON detected the presence of iron overload in most patients with mild iron overload, but not minimal iron overload.

CLINICAL RELEVANCE/APPLICATION

Two-point DIXON and R2* multi-echo DIXON are complimentary in evaluation of hepatic steatosis. Multi-echo DIXON has a higher failure rate due to fat-water swap.

SSG05-05 Optimal Simultaneous Multislice Diffusion-Weighted Imaging of Liver: Measurement of Different Breathing Schemes in Comparison to Standard Sequences

Tuesday, Nov. 27 11:10AM - 11:20AM Room: S503AB

Participants
Yigang Pei, MD, Changsha, China (*Presenter*) Nothing to Disclose

For information about this presentation, contact:

xypyg0731@163.com

PURPOSE

To obtain the optimal Simultaneous Multislice (SMS) - accelerated diffusion- weighted imaging (DWI) of liver by systematically estimating the reproducibility of apparent diffusion coefficient (ADC), signal-to-noise ratio (SNR) and image quality of different breathing schemes(DBS) in Comparison to Standard DWI Sequences in healthy volunteers.

METHOD AND MATERIALS

In this institutional review board-approved prospective study, DWIs (b=50,300,600 sec/mm2) of the liver were performed in 23 volunteers at 3.0 T MRI using three SMS accelerated DWI sequences with respiratory-triggered (RT-SMS), free breathing (FB-SMS) and breath-hold (BH-SMS), and three Standard DWI (STD) sequences with three DBS techniques (RT-STD, FB-STD,BH-STD) served as reference. Reduction of scan time by SMS-acceleration was measured. Three representative sections-superior, central, and inferior-were selected on right liver lobes respectively, three regions of interest were drawn on each selected section. ADCs and SNRs were measured and image quality were assessed on SMS and STD with three DBS. Qualitative and quantitative parameters were compared using Bland-Altman method, Friedman test and Dunn-Bonferroni post-hoc method with P-values < 0.05 considered statistically significant.

RESULTS

SMS-DWI provided diagnostic image quality with three DBS with a obviously reduction of scan time for each slice scan(1.8 vs. 4.0 sec in RT, 2.3 vs. 4.1sec in FB, 1.1 vs. 1.7 sec in BH). Overall image quality did not significantly differ between STD and SMS sequences acquisition (median RT-STD: 5.0, FB-STD: 4.5, BH-STD :5.0; RT-SMS: 4.75; FB -SMS: 4.5; BH-SMS: 4.75; P>0.0.5). SNR in the right hepatic lobe was comparable between the six tested sequences. RT-SMS have a greater SNR ADC value than RT-STD (82.3 ± 13.2 ×10-6mm2/s vs. 42.2 ± 8.6×10-6 mm2/s; P < 0.001),but FB- SMS and BH-SMS were lower in FB-STD and BH-STD respectively (FB: 56.5 ± 8.7 ×10-6mm2/s vs. 61.3 ± 12.4×10-6 mm2/s; P= 0.035; HB: 71.5 ± 6.7 ×10-6mm2/s vs. 74.5 ± 5.4×10-6 mm2/s; P =0.257).

CONCLUSION

SMS-acceleration provides considerable scan time reduction for hepatic DWI with equivalent image quality compared to the STD technique. In DBS-SMS, RT-SMS as optimal SMS sequence is recommended for liver DW imaging because of its SNR and excellent image quality, good ADC reproducibility and shorter acquisition time.

CLINICAL RELEVANCE/APPLICATION

RT-SMS should be recommended for liver DW imaging.

SSG05-06 Intravoxel Incoherent Motion Diffusion-Weighted Imaging for Preoperative Assessment of Microvascular Invasion in Hepatocellular Carcinoma

Tuesday, Nov. 27 11:20AM - 11:30AM Room: S503AB

drweiyi057@163.com

PURPOSE

To prospectively evaluate the potential role of Intravoxel incoherent motion diffusion-weighted imaging and conventional radiologic features for preoperative prediction of MVI of HCC.

METHOD AND MATERIALS

115 patients with 135 newly diagnosed HCCs between January 2016 and April 2017 were evaluated. For all examinations, studies were carried out by using a 3.0 T MR system (Discovery MR 750, GE Healthcare, Milwaukee, USA). IVIM was performed by using an echo-planner imaging sequence with respiratory gating, twelve b values of 0, 10, 20, 40, 80, 100, 150, 200, 400, 600, 800 and 1000 sec/mm2 (with number of excitations of 1, 6, 4, 2, 2, 2, 1, 1, 2, 4, 6 and 6, respectively) were obtained. All the IVIM images were analyzed by two independent radiologists independently. Freehand region of interest (ROI) was used to outline the tumor on the original IVIM image (b=400 sec/mm2), and try to avoid the necrosis and hemorrhage The ADC, ADCslow, ADCfast and f values were automatically calculated. Univariate and multivariate logistic regression analyses were used to screen the independent risk factors of MVI, receiver operating characteristics (ROC) curves were drawn and to determine the optimal cut-off value. A P value less than 0.05 was considered to indicate a statistical significance.

RESULTS

Features significantly related to MVI of HCC at univariate analysis were reduced ADC (odds ratio, 0.341, 95% CI: 0.211-0.552; P<0.001) and ADCslow (odds ratio, 0.141, 95% CI: 0.067-0.299; P<0.001). At multivariate analysis, only ADCslow was the independent risk factor for MVI of HCC. The mean ADCslow value for MVI of HCC showed an area under ROC curves of 0.815 (95% CI: 0.740-0.877) with the optimal cutoff value of 0.868.

CONCLUSION

The results of the preliminary study have demonstrated that the decreased ADCslow value was independent risk factor for predicting MVI of HCC.

CLINICAL RELEVANCE/APPLICATION

1. IVIM can be used to predict the MVI of HCC.2. The result of ADCslow measurement with an optimal cutoff point of 0.868 was preliminary, and the decreased ADCslow should be considered when developing a treatment strategy for HCC.

SSG05-07 Cross Vendor Validation of Multi-point Dixon MRI for Fat Detection: A Phantom Study

Tuesday, Nov. 27 11:30AM - 11:40AM Room: S503AB

remere1@ccf.org

PURPOSE

The amount of visceral adipose is increasingly recognized to impact a wide variety of disease processes. We assessed multi-point Dixon pulse sequence in multiple platforms for accuracy and reproducibility.

METHOD AND MATERIALS

7 fat-water phantom sets (0%, 10%, 20%, 40%, 60% and 100% fat) were created and analyzed at on one MRI system (3T Siemens Skyra). 6 phantom sets were distributed to Visceral Adiposity and Physical Fitness in CKD study sites that used 2 Siemens 3T Skyra, 1 Siemens 3T Prisma, 1 Siemens 1.5T Avanto, 1 GE Discovery 3T MR750, and 1 Philips 3T Ingenia. Phantoms were scanned using commercially available 6 point Dixon sequences once for quality assurance at study initiation and subsequently during every subject exam over the 24 months of the study. Summary statistics include cross-sectional accuracy (by weight), short term test-retest reproducibility, and long term test-retest reproducibility for the entire study, for each site, for each manufacturer and for each system type.

RESULTS

391 patients were scanned and phantoms were evaluable in 361 (92%). 99 phantoms were scanned on Siemens 1.5, 115 Siemens 3T, 60 Philips 3T, 87 GE 3T. Average measured fat % (±s.d.) for 100% phantom was 96.2 (±2.8), for 35% phantom was 36.9 (±5.0), for 16% phantom was 18.6 (±5.0), for 10% phantom was 9.9 (±4.3) and for 0% phantom was 2.6 (±3.1). Average % error across all phantom percents for each platform was: 2.7% Siemens 1.5, 2.1% Siemens 3, 3.8% Philips, 1.9% GE.

CONCLUSION

6 point Dixon MRI is highly accurate in quantifying fat percent irrespective of vendor or magnet strength.

CLINICAL RELEVANCE/APPLICATION

6-point Dixon can be used to quantify body fat accurately on multiple vendors.

SSG05-08 Pre-Operative Prediction of Hepatocellular Carcinoma Recurrence After Hepatectomy Using Intravoxel Incoherent Motion (IVIM)

For information about this presentation, contact:

wangjin3@mail.sysu.edu.cn

PURPOSE

To investigated the diagnostic performance of intravoxel incoherent motion (IVIM)-diffusion-weighted imaging in predicting posthepatectomy recurrence in hepatitis B virus (HBV)-infected adults with hepatocellular carcinoma (HCC).

METHOD AND MATERIALS

With institutional review board approval and informed consent requirement waiver, we retrospectively identified 157 patients who underwent 3.0T IVIM-based diffusion-weighted imaging within one month before hepatectomy for HCC between 2014-2017. HCC with clean margins was confirmed in each hepatectomy specimen. IVIM derived-parameters including apparent diffusion coefficient (ADC), diffusion coefficient (D), pseudodiffusion coefficient (D*), and perfusion fraction (f) were obtained. Regions of interest (ROIs) were drawn manually to encompass as much of the lesion as possible in the maximum tumor cross section and placed at least 5 mm far away from the margin of the lesion and avoided necrosis and hemorrhage. Image analysis was performed independently by two abdominal radiologists who were blinded to pathologic and follow-up. Disagreements were adjudicated in consensus. Pathology was reviewed for each resected HCC by a hepatopathologist. Tumor recurrence was determined by clinical and imaging follow up. The cut-off values of IVIM parameters were determined by receiver operating characteristic (ROC) analysis. IVIM parameters and clinical factors were analyzed the potential predictors for postthepatectomy recurrence using Cox proportional hazards model.

RESULTS

The optimal cut-off values of ADC, D, D*, and f for predicting recurrence of HCC were 0.858 × 10-3 mm2/s, 0.985 × 10-3 mm2/s, 12.5 × 10-3 mm2/s, and 23.4%, respectively. Lower ADC, D, and f values were associated with poor histologic differentiation of HCC (P < 0.001 - 0.001) and the f value was related to microvascular invasion (P = 0.0017). The D value [hazard ratio (HR), 0.190; P = 0.023], age (HR, 0.328; P = 0.034), A-fetoprotein (AFP) (HR, 2.079; P = 0.013) were independently predicted tumor recurrence after hepatectomy resection.

CONCLUSION

In HBV-infected adults with HCC, D value, age and AFP independently predicted tumor recurrence.

CLINICAL RELEVANCE/APPLICATION

Although preoperative IVIM are independent predictors of posthepatectomy recurrence. This finding needs to be further confirmed in the future.

SSG05-09 Compressed Sensing Reconstruction of High Resolution Hepatobiliary Phase Imaging at Gadoxetic Acid-Enhanced Liver MRI: A Feasibility Study

Tuesday, Nov. 27 11:50AM - 12:00PM Room: S503AB

Awards
Student Travel Stipend Award

Joon Koo Han, MD, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the clinical feasibility of high resolution (HR) hepatobiliary phase (HBP) imaging using compressed sensing (CS) reconstruction of gadoxetic acid-enhanced liver MRI (Gd-EOB-MRI)

METHOD AND MATERIALS

This retrospective study included 136 patients who underwent Gd-EOB-MRI at one of two 3T scanners (Ingenia or Ingenia CX, Philips) including three breath-hold HBP sequences: i) standard HBP using mDixon-3D-fast field echo (FFE) (S-HBP), ii) HR HBP using mDixon-3D-FFE (HR-HBP), and iii) HR HBP using CS reconstruction (CS-HR-HBP). Acquired resolutions were i) 1.2x1.3x3.0 mm and ii-iii) 1.0x1.0x1.5 mm). HBP images were obtained with either protocol A (Ingenia CX) using acceleration factors (AFs) for S-HBP, HR-HBP and CS-HR-HBP of 2.8, 6.14 and 6.4, and acquisition times of 13.1, 12.4, and 12.9 sec for S-HBP, HR-HBP, and CS-HR-HBP (n=58), or protocol B (Ingenia) using AFs of 2.8, 3.4 and 6.4 and acquisition times of 15.3, 17.2, and 14.2 sec (n=78), respectively. Image quality and diagnostic performance in detecting solid focal liver lesions (FLLs) were compared among the sequences.

RESULTS

Using protocol A with similar acquisition times between CS-HR-HBP, S-HBP, and HR-HBP, CS-HR-HBP showed significantly better overall image quality and lesion conspicuity than the other sequences (Ps <0.05). Using protocol B with a shorter acquisition time in CS-HR-HBP than in S-HBP or HR-HBP, CS-HR-HBP showed comparable results in overall image quality and lesion conspicuity to the other sequences (Ps>0.05), albeit with more severe unzip artifacts than S-HBP (P=0.003). Moreover, the performance of CS-HR-HBP in detecting solid FLLs using protocol A, was better than S-HBP (reader-averaged figures-of-merit (FOM); 0.92 vs. 0.82, P=0.02), while CS-HR-HBP using protocol B was equivalent to S-HBP or HR-HBP (0.86 vs. 0.80 or 0.90; Ps=0.06, 0.23, respectively).

CONCLUSION

CS-HR-HBP was demonstrated to be feasible, providing better image quality and higher performance in detecting solid FLLs at similar acquisition times to S-HBP and HR-HBP. When using shorter acquisition times for CS-HR-HBP, its performance in detecting solid FLLs was comparable to S-HBP and HR-HBP.

CLINICAL RELEVANCE/APPLICATION

Compressed sensing can provide higher resolution and/or faster imaging acquisition, potentially aiding patients who have difficulty sustaining a breath-hold during the entire nonaccelerated imaging.

PURPOSE

Reliably identifying and communicating urgent radiology findings are crucial to the diagnosis and treatment of diseases. We describe a deep learning algorithm to automatically detect urgent radiology findings from free-text reports and evaluate its performance on a multi-institutional corpus.

METHOD AND MATERIALS

Radiology reports of 156,992 studies from Nov. 2017 to Feb. 2018 were collected from 3 hospitals. These reports were categorized by experts using 4 levels of acuity (1=normal, 2=routine, 3=priority and 4=critical). Reports also received a binary label as requiring follow-up or not. We randomly stratified the reports into a 70% training, a 10% validation, and a 20% test set. For classification we developed a 2-layer long short-term memory (LSTM) network followed by a term weighting layer. We then use the weighted sum of the LSTM states as a vector representation of the report to get the probabilistic estimate of the urgency level. To enable knowledge transfer from a larger corpus, we trained word vectors with the GloVe algorithm on 4.5 million reports and use them to initialize the word vectors used in our network. Additionally, the term weighting layer provided interpretable information about which words were weighted most heavily towards the decision.

RESULTS

We evaluate our algorithm on 3 tasks: (1) binary classification of the reports into urgent (categories 3-4) vs. non-urgent (categories 1-2) findings; (2) binary classification into follow-up vs. non-follow-up recommended; and (3) 4-way classification for acuity categories 1-4. Results for task 1, 2, and 3 are AUC=0.951, AUC=0.961, and micro-averaged F1=0.846, respectively. In comparison, a baseline naive Bayes classifier with hand-tuned lexical features achieves 0.911, 0.915, and 0.773 for the 3 tasks. Task 3 F1 drops to 0.833 when we initialize the word vectors randomly, suggesting that some knowledge was transferred from the larger corpus. Term weighting results showed the network placed a high weight on 'no abnormalities' for normal studies or 'large effusion' for priority studies.

CONCLUSION

Deep learning algorithms can reliably detect urgent radiology findings from free-text radiology reports and provide highly interpretable results.

CLINICAL RELEVANCE/APPLICATION

Automatic detection of urgent radiology findings with natural language processing and deep learning is a useful technique for

improving clinical radiology workflow.

SSG06-02 Automated Determination of Radiology Reports Requiring Urgent Communication Using Intelligent Word Embeddings

CONCLUSION

The model performed extremely well at the task of detecting urgent findings in radiology reports. This model can be further tested in real clinical workflow to further assess its value as a detection tool.

Background

Radiology exams can reveal findings that require the immediate attention of clinicians. Radiologists are responsible for ensuring communication of urgent findings because it may affect patient safety and management. Leveraging Natural Language Processing (NLP) and machine learning (ML) techniques, we developed a model that can predict the likelihood that a radiology report contains findings that require urgent communication.

Evaluation

80,649 radiology reports from a variety of modalities and body parts were extracted from a single institution. Reports were labeled as containing urgent findings if the impression included phrases like 'results communicated to'; these phrases were then removed from the reports to blind the model to ground-truth. Feature selection followed the 'Intelligent Word Embeddings' model: applying standard tokenization, performing negation and phrase identification, using RadLex for synonym detection, and training fastText document embeddings on the processed reports. A variety of different classifiers (convolutional neural network, support vector machine, random forests, and multi-layer perceptions (MLP)) were trained on the document embedding vectors. The accuracies of the classifiers were compared on an internal test set of 8,779 reports and an external test set from a different hospital of 20,208 reports.

Discussion

The linear bag-of-words MLP was the best performing model, achieving an ROC-AUC of 0.94 on validation data, which corresponded to 84% accuracy at 90% sensitivity and an F1 score of 0.87. The model also achieved ROC-AUCs of 0.90 and 0.87 on the internal and external test data, respectively. A web version of the model is also provided for real-time and crowdsourced review: bit.ly/2Ikhce1

SSG06-03 Rule-Based Natural Language Processing Algorithm for Automated Parsing of Clinical Radiology Reports

PURPOSE

Clinical radiology reports are usually written in free-form text rather in a structured format. In this work, we develop and validate rule based natural language processing (NLP) algorithm to parse these reports into structured data consumable by other information systems.

METHOD AND MATERIALS

Anonymized clinical radiology reports of 290,155 (development dataset) and 1,779 (Q2k dataset) head CT scans were used to develop and validate the algorithms. Target findings were intracranial hemorrhage and its subtypes, intraparenchymal, intraventricular, subdural, extradural and subarachnoid hemorrhages, skull fracture, midline shift and mass effect. Rules based on keywords and regular expressions were constructed to account for the variations in reporting of the these findings in development dataset. Additionally, grammar rules were created to identify the negations in a sentence. To validate the results of this rule based algorithm, we established gold standards of Q2k dataset by manually going through them. We measure sensitivity and specificity of the algorithm for each finding against this gold standard.

RESULTS

Average sensitivity and specificity of the algorithm across the target findings on Q2k dataset are 0.9841 and 0.9956 respectively.

Least performing finding was subdural hemorrhage with sensitivity of 0.9318 (95% CI 0.8134-0.9857) and specificity of 0.9965 (95% CI 0.9925-0.9987) while skull fracture was inferred perfectly with sensitivity of 1 (95% CI 0.9745-1.000) and specificity of 1 (95% CI 0.9977-1.000). A previous similar study on head CT reports, but with machine learning based NLP algorithms, reported average sensitivity and specificity of 0.9025 and 0.9172 across findings.

CONCLUSION

In this work, we showed that rule based NLP algorithms can identify the findings from free text clinical radiology reports with very high accuracies. Their performance is superior to that of machine learning based NLP algorithms which require annotation of reports instead of rule creation.

CLINICAL RELEVANCE/APPLICATION

This algorithm can be used to retrieve studies with desired findings from a PACS for research or educational purposes, or to train AI algorithms.

SSG06-05 Restoration of Motion-corrupted MR Images Using Deep Adversarial Networks

Tuesday, Nov. 27 11:10AM - 11:20AM Room: N230B

Participants
Karim Armanious, MSc, Stuttgart, Germany (*Presenter*) Nothing to Disclose
Thomas Kuestner, DIPLENG, Stuttgart, Germany (*Abstract Co-Author*) Nothing to Disclose
Sergios Gatidis, MD, Tubingen, Germany (*Abstract Co-Author*) Nothing to Disclose
Bin Yang, PhD,DIPLENG, Stuttgart, Germany (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Motion artifacts are a frequent source of image quality deterioration in MRI. Existing motion correction strategies mostly focus on prospective compensation of motion artifacts during acquisition. Currently, strategies for retrospective correction of acquired MR images are very limited. The purpose of this work is to implement and evaluate a framework for retrospective restoration of motion-corrupted MR images using deep adversarial networks.

METHOD AND MATERIALS

Our proposed framework consists of two main components trained simultaneously. The first component is a multi-scale deep architecture consisting of 70 convolutional layers for high-resolution image restoration of MR images.The second component is a convolutional neural network (CNN), which classifies the output of the first multi-scale network as realistic or not. The training of the network is done in the adversarial fashion of generative-adversarial networks, where competition between the two components drives the multi-scale network to improve its performance until a detailed motion-free MR image is acquired. The framework was trained on a dataset of 1500 T1 weighted MR images of the head and pelvis regions from 11 volunteers. Image data were paired such that a motion-free and a motion-corrupted image were acquired. Evaluation of the trained model was carried out on a separate dataset of 600 MR images from 4 patients. The quality of the motion corrected images was attested quantitatively in comparison to MR images without motion correction using the SSIM metric. Additionally, qualitative performance was rated by 2 radiologists using a 4-point score (4: best).

RESULTS

The developed framework achieved state-of-the-art results on MR motion correction for rigid motion artifacts. Motion-corrected images achieved an average score of 2.9 by radiologists in comparison to 1.2 for images without motion correction and to 3.7 for motion-free MR images. In addition, SSIM score of motion corrected images has improved by 27.3 % indicating a remarkable reduction of artifacts.

CONCLUSION

Motion artifacts can be retrospectively corrected using a deep adversarial framework, enabling a high-resolution restoration of MR images.

CLINICAL RELEVANCE/APPLICATION

This project enables the extraction of valuable information from motion-corrupted MR images. This can be used to enhance the accuracy of post-processing tasks, such as segmentation and organ volume estimation.

SSG06-06 Predicting Exam Cancellations Using Machine Learning: Towards Optimized Radiology Scheduling

Tuesday, Nov. 27 11:20AM - 11:30AM Room: N230B

Participants
William Hsu, PhD, Los Angeles, CA (*Presenter*) Research Grant, Siemens AG
Jay Won, Los Angeles, CA (*Abstract Co-Author*) Nothing to Disclose
Sarah E. Luery, Los Angeles, CA (*Abstract Co-Author*) Nothing to Disclose
Cleo K. Maehara, MD, Brookline, MA (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

whsu@mednet.ucla.edu

PURPOSE

The capacity of a radiology department is constrained by the number of imaging slots, which is related to the availability of imaging equipment. However, while slots may be filled in advance, last minute cancellations and no-shows may result in underutilization that could have otherwise accommodated additional patients. We evaluated the use of a machine learning approach called gradient boosting trees that were trained on scheduling and medical record data to predict whether an exam would be canceled.

METHOD AND MATERIALS

Using data from 150,000 past scheduled exams during a 2 year time period, we examined whether each exam was completed or

canceled. Metadata about an exam such as its description, modality, anatomical region, duration, site/location, patient demographics (age, gender, associated diagnostic codes), and timestamps (date of scheduling, exam completion) were used as inputs to the model. For each cancellation, we recorded the date and reason. A gradient boosting is a machine learning method that generates a set of decision trees from training data by minimizing the average value of a loss function and incrementally expanding the model. A final prediction is generated based on the collective sum of each tree's prediction. A five-fold cross-validation was used to train and test the model. A random sample of 6,000 exams was set aside from each training set to tune the model hyperparameters.

RESULTS

A total of 44,928 exams (30%) were canceled, many of which are provider-initiated (e.g., erroneous order). Of the canceled exams, 13,962 (31%) were canceled by the patient (in advance or no-show). The average area under the curve across all of the folds was 0.742 +/- 0.004. The most predictive features included patient age, day/time of the scheduled exam, location, and whether the exam was an x-ray or ultrasound.

CONCLUSION

We demonstrate a prediction model with a limited set of clinical and exam variables is still capable of yielding meaningful predictions. We are exploring other factors such as the distance of the patient to the imaging site, weather and traffic, prior history of cancellations, and payor as ways to improve the model's accuracy.

CLINICAL RELEVANCE/APPLICATION

A model to predict exam cancellations may assist departments with identifying and avoiding such occurrences through outreach (e.g., proactive reminders) and mitigation of underlying issues (e.g., difficulty coming to the site, denial by payors).

SSG06-07 Generative Adversarial Neural Networks in the Creation of Synthetic Chest Radiographs: Can We Fool the Experts?

ayis.pyrros@dupagemd.com

PURPOSE

Generative Adversarial Neural Networks (GANs), are a form of unsupervised machine learning, utilizing competitive neural networks, which can synthesize realistic images unique from training data. GANs can theoretically allow a near limitless supply of unique and HIPAA compliant cases, which could be used for both computer and human training. The purpose of this study was to determine if chest radiographs synthesized from a GAN could fool radiologists.

METHOD AND MATERIALS

A GAN was trained using a sliced Wasserstein distance criterion, with modifications to suppress variance in the estimate of the sliced Wasserstein distance. Training data is the NIH Chest X-ray8 dataset, using 60,000 images. All frontal radiographic views were used regardless of findings. Synthetic radiographs, 512x512 pixels, were created in PNG format. De novo real/acquired chest radiograph images and synthetic images were randomly assorted into testing sets consisting of pairs of one real and one synthetic image, with the same resolution. These images were then presented to 12 ABR-certified radiologists, with a median experience of 10-15 years. The radiologists were then asked to distinguish between synthetic and real images using a two-alternative forced choice, with random timers between 2-10 seconds. Subjects were presented with as many pairs as they were willing to judge.

RESULTS

GAN training took approximately 70 hours on an NVIDIA P100. The generation of a synthetic image takes on average 2ms on an NVIDIA Titan-X. Overall, expert readers were able to detect the synthetic image in 61% of over 1300 pairs viewed (chance is 50%; this corresponds to a sensitivity of 61% and a specificity of 39%). There is significant variation between subjects, with some subjects reliably able to identify real images quite accurately (3 % of GAN images identified as real) and others reliably detecting GAN images as real (85%).

CONCLUSION

Current GAN methods can generate unique realistic chest radiographs in arbitrary quantities. These radiographs can pass as real images, when presented to radiologists.

CLINICAL RELEVANCE/APPLICATION

Current applications include anonymizing datasets and training images for humans and machines. Improvements could allow generating images guaranteed to contain a particular disease, to show a rare disease state, enhance image quality, create unique views, or to show possible future disease states implied by a current radiograph.

SSG06-08 Realistic CT Images Generation Using Condition Generative Adversarial Network (cGAN) for Accurate Segmentation of Hemorrhagic Stroke

Tuesday, Nov. 27 11:40AM - 11:50AM Room: N230B

Participants

Junghwan Cho, PhD, Lowell, MA (*Abstract Co-Author*) Nothing to Disclose
Eunmi Lee, Lowell, MA (*Abstract Co-Author*) Nothing to Disclose
Seokhwan Ko, Lowell, MA (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

mkarki@caidesystems.com

PURPOSE

Investigate the quality of synthetic brain CT images generated using a cGAN, and their use as augmentation data for accurate detection and dilineation of hemorrhagic stroke.

METHOD AND MATERIALS

Well labeled intracranial hemorrhage on 33391 CT images from 2647 patients consisting of 5 subtypes: intraparenchymal, intraventricular, subarachnoid, epidural and subdural hemorrhages were obtained. Existing GAN implementation on tensorflow framework and images of 256 x 256 were used. Images from 80% of patients were used for training and 20% set aside for testing. Segmented ground truth images were used as the condition to steer the generation process. 2.5%, 10% and 50% of original training data were trained for 10, 50, 100 and 200 epochs each. Because evaluating generated images using a single traditional metric did not reflect the quality of images well, we used a combination of metrics. FCN Scores, Clarity (based on average blurriness) and a classifier that distinguishes between generated images and original images at various thresholds were used. FCN scores were obtained by evaluating the dice similarity coefficients (DSC) of generated images on an existing segmentation algorithm specifically trained only on the original dataset. The best GAN model chosen was then used to generate additional images as training to improve a fully convolutional neural network (FCN) for segmentation.

RESULTS

Using 2.5% of original data, generated images helped to increase sensitivity by 16.7% and DSC by 38%. The increase using 10% of original data was 56.5% and 28.8% for sensitivity and DSC respectively. Whereas using 50% of original data, the increase was 26.7% and 22.6% for sensitivity and DSC respectively.

CONCLUSION

Conditional GANs were effective in generating realistic images that increased detection and delineation performance compared to model trained with just original data. Both dice coefficients and sensitivity increased with the usage of synthetic CT images as augmentation.

CLINICAL RELEVANCE/APPLICATION

Realistic synthetic images generated from accurate labels could help studies and medical tools that rely on access to labeled medical images for training and validation.

SSG06-09 Self PET Attenuation Correction Using Conditional Generative Adversarial Networks

Tuesday, Nov. 27 11:50AM - 12:00PM Room: N230B

Participants
Karim Armanious, MSc, Stuttgart, Germany (*Presenter*) Nothing to Disclose
Marc Fischer, MSc, Stuttgart, Germany (*Abstract Co-Author*) Nothing to Disclose
Bin Yang, PhD,DIPLENG, Stuttgart, Germany (*Abstract Co-Author*) Nothing to Disclose
Sergios Gatidis, MD, Tubingen, Germany (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Current methods for PET attenuation correction rely on the existence of an attenuation map generated by a second imaging modality which is mostly CT. In certain situations, CT is not available and attenuation correction is performed by estimating an attenuation map using MRI or by importing externally acquired CT images. In this work, we present and evaluate a framework for self attenuation correction of PET data using conditional Generative Adversarial Networks (cGAN) which does not require an accompanying modality.

METHOD AND MATERIALS

The principle idea of the proposed method is to generate an artificial CT image only based on non-corrected PET data. This CT image can then be used for subsequent PET attenuation correction. Our method is based on a cGAN trained on a dataset of corresponding PET/CT brain images from 38 patients. The cGAN consists of three separate convolutional neural networks (CNNs). The first network translates an uncorrected PET image into a synthetic corresponding CT image. The two remaining networks compare the low and high-frequency components respectively between the synthetically generated CT images and the ground-truth CT images. As a result, the generator network is able to match the global structure as well as the texture and style of the desired output. The proposed method was evaluated on a dataset of PET/CT images of the head region from 8 patients. Quantitative comparison between synthetic and ground truth CT images was carried out using the Structural SIMilarity (SSIM) index. In addition, qualitative performance to judge the clinical fidelity of the synthetic CT images was rated by 2 radiologists using a 4-point score (4: best).

RESULTS

The developed method succeeded in translating uncorrected input PET images into highly realistic synthetic CT images. The image quality of synthetic CT images received an average score of 3.1 by radiologists in comparison to 3.7 for real images. Quantitative correlation between our synthetic CT images and corresponding ground truth CT images is indicated by an SSIM score of 0.914.

CONCLUSION

Attenuation correction of PET images without further image modalities is feasible and could be achieved by utilizing cGANs.

CLINICAL RELEVANCE/APPLICATION

The proposed method can be used for fast and reliable attenuation correction of PET data in situations where no CT can be

acquired for this purpose. An extension to whole body imaging is conceivable.

ingrid.leguerney@gustaveroussy.fr

PURPOSE

To develop a reliable in vivo model to assess by ultrasound and MRI imaging tumor development and local molecular expressions

METHOD AND MATERIALS

The model used is a patient derived xenograft: an 8 mm tumor core is taken from fresh renal cell carcinoma (RCC) at the time of surgery. The tissue sample is cut into 300 µm homogenous slices with a dedicated device (Krumdieck, Alabama Research & Development). Each slice is grafted into the kidney capsule on immunodeficient mice (RAG2-/-γc-/-) in order to develop a cohort from the same tumor. The grafted tumor is then monitored by ultrasound imaging (Aplio, Toshiba and VEVO2100, Visualsonics) and 7T MRI (Bruker spectrometer). Once the tumor is detected, a first 7T is made to accurately measure the tumor volume and ultrasound molecular imaging series are performed. US molecular imaging is based on antibody -related contrast agents (MicroMarker™, Visualsonics). The antibodies selected for our RCC study are VEGFR1 and FSHR. The targeted signal enhancement is quantified and compared to the signal of the non-targeted microbubbles 10 minutes after the injection. Ultrasound imaging is performed the same week as MRI (T0), then at 1week, 2 weeks and one month on two groups placebo versus sunitinib. Before sacrifice of animals, a second MRI is also performed.

RESULTS

Slices of tumors from 7 patients were removed and implanted on mice. To date, 5 cohorts from 3 different patients have been treated and imaged by ultrasound and MRI. Ultrasound examinations with non-targeted microbubbles validated the lack of specificity of these agents over time for both the placebo and sunitinib groups. On the other hand, the quantification of VEGFR1 and FSHR showed a decrease in the expression of these biomarkers in the sunitinib group, particularly at 1 week and 2 weeks compared to the placebo group. According to the cohorts, the decreases observed are of the order of a factor between 2 to 17.

CONCLUSION

Xenografts derived from patient samples are more realistic models for molecular imaging studies. These first results are encouraging for the follow-up of biomarkers of interest in oncology.

CLINICAL RELEVANCE/APPLICATION

Robust and realistic preclinical models are essential for better-adapted clinical trials and the identification of biomarkers that can guide therapeutic strategies.

SSG07-02 Human Somatostatin Receptor type-2 (hSSTR2) Mutant Muted in Altering T-Cell Signaling and Function Enables Visualization of T-cell Trafficking

vkundra@mdanderson.org

PURPOSE

Adoptive T-cell therapies have shown great promise in patients, but are limited by clinically translatable methods for following their trafficking in vivo. Reporters (enzymes, transporters, receptors) can alter T-cell cellular milieu and function. We evaluated whether a hSSTR2 mutant reporter is signaling deficient in T-cells and can serve to image these cells in vivo.

CONCLUSION

A hSSTR2 mutant muted in altering OT1 T-cell signaling or function can serve as an in vivo reporter of T-cells trafficking.

CLINICAL RELEVANCE/APPLICATION

Findings suggest that the hSSTR2-based mutant reporter muted in signaling has potential for clinical translation for following adoptive T-cell therapy without affecting T-cell function.

SSG07-03 Out of Sight, Out of Mind: The Detection Rate and Impact on Management Intent of 68Ga-PSMA-HBED-CC PET/CT in Prostate Cancer - Results from a Brazilian Center

PURPOSE

The aim of this study was to evaluate the detection rate and the role of PSMA PET/CT on management intent in patients with primary or recurrent prostate cancer.

METHOD AND MATERIALS

A retrospective study of 251 patients who underwent PSMA PET/CT imaging for primary staging and for biochemical recurrence between June and December 2017 was performed. All patients were submitted to the same imaging protocol and were reviewed together by a nuclear medicine physician and a radiologist with at least five years of experience. We conducted a retrospective survey of referring physicians who completed one questionnaire to indicate the initial treatment plan without PSMA PET/CT information and after the scan to denote intended management changes.

RESULTS

Overall 173 PSMA PET-CT studies were performed for biochemical relapse (69%) and 78 (31%) for primary staging. Median total PSA was 9,63 ng/ml (0,099-259,0 ng/ml). The median Gleason-score was 7 (range 4-10). The overall percentage of positive PSMA PET-CT among patients was 70%. In 38 patients (15,1%) no abnormal findings were observed. The average maximum standardized uptake value (SUV) was 16,7 (range 1,8 - 107,3). PSMA PET/CT revealed unsuspected disease in the prostate bed in 12,4% of patients, locoregional lymph nodes in 34,7% (57% were up to 1 cm), and distant metastatic disease in 16,3%. Considering PSA ranges, 3 % of patients had positive scans with PSA up to 0.2, 22% with PSA from 0.2-1.0, 12% with PSA from 1.0-2.0, and 63% positivity with PSA above 2.0 ng/ml. Overall, PSMA PET/CT scanning led to 38.2% change in planned management. The impact was greater in the biochemical failure group (47% change in management intent, most these consisted of conversion from systemic treatment to focal treatment) than in patients undergoing primary staging (19%).

CONCLUSION

The early and accurate detection of prostate cancer disease is important to ensure timely management and appropriate individualized treatment. Currently, conventional imaging has limitations particularly in early disease detection in biochemical failure patients, especially at PSA level < 2.0 ng/mL. PSMA-PET/CT has high diagnostic accuracy for small lymph node, especially at low PSA levels.

CLINICAL RELEVANCE/APPLICATION

68Ga-PSMA-HBED-CC PET/CT is superior to conventional imaging methods, especially at low PSA levels (under 2.0 ng/mL), for early detection of metastases, thereby significantly impacting on appropriate treatment.

PURPOSE

To evaluate the histological correlates of PSMA PET/CT findings in a mixed cohort of high risk, biochemically recurrent (BCR), and metastatic prostate cancer (PCa) patients.

METHOD AND MATERIALS

Patients enrolled on a clinical trial to evaluate PSMA PET/CT imaging in PCa undergo 18F-DCFPyL PET/CT imaging, along with multiparametric MRI (mpMRI) for patients negative for metastases on conventional imaging (CIM) or 18F-NaF PET/CT for patients with suspicious findings for metastatic disease on CIM. PSMA PET/CT imaging was prospectively interpreted by an experienced nuclear medicine physician. When feasible, patients underwent a core-needle biopsy by image-guidance (CT or US) of regions suspicious for metastases by study imaging. For patients undergoing CT-guided biopsy, biopsy targeting localization was confirmed by anatomical registration with PSMA PET/CT imaging.

RESULTS

Samples were obtained from 18 patients, including 12 patients with negative CIM (5 high-risk [median PSA 18.87], 7 BCR [median PSA 2.08 ng/ml]) and 6 patients with positive CIM (2 high-risk, 4 metastatic [median PSA 12.16 ng/ml]). Twenty-two lesions were sampled from bone (N=11), lymph nodes (N=9), or other soft tissue areas (N=2). PSMA PET/CT findings in these lesions were prospectively interpreted as negative (N=4), indeterminate (N=4), or positive (N=14). PSMA negative or indeterminate lesions were not found to harbor metastatic PCa, with 5/8 samples demonstrating non-cancerous pathologies including fibrous dysplasia, reactive node, and lung carcinoma. Of 14 PSMA-positive samples, 11 were confirmed metastatic PCa, 2 demonstrated an alternative pathology (focal fibrosis in bone and necrosis/inflammation in a node), and one was negative (hematopoietic bone). Patients with solitary findings outside of prostate area were less likely to harbor metastatic PCa (p=0.05). SUVmax was higher in cancer sites (median 30, range 3.7-77, p=0.01); however, SUVmax differed in non-cancerous DCFPyL-avid nodal sites (SUVmax<3) compared to non-cancerous DCFPyL-avid bone sites (SUVmax range 2.5-6.7).

CONCLUSION

Preliminary findings of this ongoing study demonstrates an elevated frequency of non-cancerous benign pathologies with differential DCFPyL uptake based on anatomical locations.

CLINICAL RELEVANCE/APPLICATION

Non-specific PSMA uptake has been noted in several recent studies, further pathological validation and characterization of imaging signatures is warranted.

SSG07-05 Correlation Between Diffusion-weighted MRI and Proliferative Activity ki-67 Expression in Cervical Cancer Cells

Tuesday, Nov. 27 11:10AM - 11:20AM Room: S504CD

Participants
Zhen Ma, Zhengzhou, China (*Presenter*) Nothing to Disclose
Jingliang Cheng, MD,PhD, Zhengzhou, China (*Abstract Co-Author*) Nothing to Disclose
Yong Zhang, DO, Zhengzhou, China (*Abstract Co-Author*) Nothing to Disclose
Shuo Zhang, MMed, Zhengzhou, China (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To investigate the changes of ADC value and rADC value of diffusion-weighted magnetic resonance imaging (DWI) in patients with cervical cancer with different differentiation degrees and their correlation with proliferative activity ki-67 of cervical cancer cells.

METHOD AND MATERIALS

Forty patients with cervical cancer were diagnosed by pathology. All the patients underwent MR examination and diffusion-weighted imaging before operation, and Ki-67 immunohistochemical staining was performed during the operation.The expression of ki-67 in cervical cancer patients with different differentiation degrees was analyzed by means of ANOVA. Pearson correlation analysis was used to analyze the correlation between Ki-67 and ADC and rADC values.The statistical analysis of data by SPSS 20.0 software has statistical significance ($P < 0.05$).

RESULTS

The ADC value and rADC value of low differentiation group were lower than that of high differentiation group, the difference was statistically significant (P < 0.05).There was no significant difference between the low differentiation group and the middle differentiation group (P > 0.05).With the degree of differentiation, the expression of Ki-67 increased gradually.With the increase of Ki-67 expression degree, the ADC value and rADC value decreased, and the difference was statistically significant (P < 0.05). After the correlation test, it was found that there was a negative correlation between ADCs value and Ki-67 expression degree (P < 0.05).

CONCLUSION

The measurement of DWI value in cervical carcinoma is helpful to evaluate and differentiate the pathological grade of cervical cancer and has the potential as a noninvasive method to evaluate the degree of tumor proliferation.

CLINICAL RELEVANCE/APPLICATION

The grade of cervical cancer was distinguished by the correlation between DWI and ki-67

SSG07-06 PET Proliferation Imaging Biomarkers for Monitoring Treatment Response of Combined Cyclin-Dependent Kinase Inhibitors and Endocrine Therapy in Breast Cancer: Comparison of FLT and ISO-1 Radiotracers

PURPOSE

Cell cycle targeted therapeutics such as CDK4/6 inhibitors (CDK4/6i) in combination with endocrine therapy are the emerging standard of care for treating metastatic ER+ breast cancer (BC). These agents target cell cycle at two independent checkpoints, therefore PET probes reflecting different facets of proliferation, seem promising for identifying patients that might benefit from addition of CDK4/6i. In this study, we compared the ability of 18F-FLT (reflecting S-phase changes) and 18F-ISO1 (reflecting proliferation), for predicting response from combination therapy with CDK4/6i (palbociclib [PD]) and ER antagonist (fulvestrant [F]).

METHOD AND MATERIALS

Six BC cell lines with different ER status and sensitivity to PD were treated with PD and/or F. Cell proliferation assay, flow-cytometric cell cycle analyses, Ki-67, and TMEM-97 western-blot were performed after 24hrs, 72hrs, and 6days. These data were correlated to FLT uptake and ISO-1 analogue ligand-binding. Subsequently, SCID mice bearing MCF7 tumors were used for in-vitro investigation and randomly assigned to PD, F, or PD+F groups. FLT and ISO-1 micro-PET/CT were performed, on days 0, 3, and 14 of treatment. Changes in tumor to muscle uptake ratios (T/M) for each tracer was quantified and correlated to changes in cell-cycle.

RESULTS

PD resulted in a remarkable decrease in FLT accumulation at all time points, correlating with decrease in S-phase. In contrast, change in binding of ISO-1 was delayed and only prolonged combination therapy in ER+ cells (MCF7 & MDA134) resulted in significant reduction ($p<0.01$), correlating with G0 arrest. On day 3 of MCF-7 xenograft treatment, FLT T/M significantly decreased in treated mice ($p<0.005$), without change in ISO1 uptake. On day 14, we noticed significant decrease in ISO-1 T/M in combination therapy group ($p<0.05$). Changes in FLT and ISO1 uptake correlated with S-phase depletion and G0-arrest, respectively, as an indication of contribution of PD and F in treatment response.

CONCLUSION

FLT and ISO-1 PET/CT assess different aspects of proliferation after PD and F treatment. Our data suggest that FLT is more sensitive in evaluating changes in tumor proliferation and provides a prediction of both early and late treatment changes, whereas ISO-1 is more predictive for late response.

CLINICAL RELEVANCE/APPLICATION

Combination of FLT and ISO-1 PET imaging might serve as a clinically translatable approach to guide dual-targeted therapy of ER+ BC.

PURPOSE

Of all soft tissues, the normal prostate has the highest mobile zinc content, but this level decreases dramatically during malignant transformation. We aimed to use iCEST (ion chemical exchange saturation transfer) 19F MRI as a non-invasive means to probe zinc depletion in prostate cancer.

METHOD AND MATERIALS

For in vitro validation studies, normal (RWPE1), ZIP1 zinc transporter-downregulated (RWPE2), and malignant (DU145 and LNCaP) human prostate cells were incubated with 75 µM $ZnSO_4$ and induced to secrete zinc using glucose stimulation. Following the addition of 2.5 mM TF-BAPTA, 19F-derivative of BAPTA which is a fluorescent dye indicator for zinc, the supernatant was assessed with 1H and 19F iCEST MRI at 17.6 T. For in vivo studies, 1E6 cancer cells were injected into the prostate of 6-8 weeks old immunodeficient NSG mice and allowed to grow for 21 days. Immediately after i.p. injection of 80 µL of 20% w/v D-glucose and injection of 0.15 g/kg bw TF-BAPTA into the anterior prostate through a catheter, iCEST MR images were collected at 17.6T using a modified RARE sequence with a FOV=2.6×2.6 cm, 3 mm slice thickness, and a resolution of 0.8x0.8 mm.

RESULTS

In vitro, the strongest iCEST signal was observed for glucose-stimulated RWPE1 cells with a normal zinc transporter level. In normal prostate cells with a downregulated ZIP1 zinc transporter (RWPE2), a weaker iCEST signal was observed. No signal could be observed for DU145 and LNCaP prostate cancer cells. In vivo, the strongest iCEST signal was observed for the normal prostate following i.p. glucose stimulation (Fig. 1). Both the normal prostate without glucose stimulation and the two orthotopic tumor models with glucose stimulation showed much weaker iCEST signal.

CONCLUSION

Using iCEST MRI, differences in glucose-induced zinc secretion between normal and malignant prostate cells can be readily detected, both in vitro and in vivo.

CLINICAL RELEVANCE/APPLICATION

Monitoring the conversion of normal prostate cells into malignant cells using iCEST 19F MRI may be further developed to diagnose prostate cancer in its earliest stages.

SSG07-08 A Novel Treatment for Neuroendocrine Tumors Hepatic Metastases with Combination Everolimus and Trans-Arterial Chemo-Embolization (E-TACE): Role of 68Ga-DOTATATE in Conjunction with CT for Tumor Load Assessment

PURPOSE

Both TACE and Everolimus are widely used for treatment of metastatic NETs. The standard protocol is to hold Everolimus 2-4 weeks prior to and following TACE. Combining both therapies has shown therapeutic benefit in a preclinical study. RECIST 1.1 is the basic treatment response assessment criteria used, yet is limited. The aim of our study was to investigate the additive value of functional imaging using 68Ga-DOTATATE PET/CT in conjunction to contrast CT in the assessment of viable tumor volume

METHOD AND MATERIALS

We retrospectively reviewed all patients who received concurrent E-TACE between September 2016 and April 2018. Only patients who underwent baseline pre-and post-TACE 68Ga-DOTATATE PET/CT were included in our study. As part of our institutional protocol, 10 mg of Everolimus/1-2 days started $\geq$ 1 month prior to TACE. RECIST 1.1 criteria were followed. Quantitative analysis of PET/CT images were performed and multiple parameters were collected including SUVmax, SUVmean, SUVpeak, binding tumor volume (BTV), and tumor binding index (TBI)

RESULTS

Among the 23 patients who underwent concurrent E-TACE therapy, 5 met our inclusion criteria. Based on RECIST, all 5 cases showed stable disease on contrast CT. Quantitative analysis of PET/CT showed significant difference between the baseline and post-treatment scans in all tested quantitative parameters (p-value < 0.05). The pre/post-treatment mean %difference in SUVmax, SUVpeak, and TBI were -49% + -16.7%, -52.5% + 0.2%, and -71% + 21.6%, respectively. A subset analysis of 2 cases that underwent embolization of one lobe was performed, comparing the quantitative parameters between the TACE treated and non-

treated lobes. There was significant difference between the reduction in TBI after combined E-TACE treatment in the TACE treated versus non-TACE treated lobe in the same patient (-71% + 21.6% versus -25% + 14%, p-value <0.0001)

CONCLUSION

E-TACE combination resulted in reduction of liver metastatic tumor load, which was significantly better than Everolimus alone. Adding functional imaging with 68Ga-DOTATATE PET/CT to the standard follow up with contrast CT has the potential to improve treatment response assessment and overcome the limitation of RECIST

CLINICAL RELEVANCE/APPLICATION

68Ga-DOTATATE PET/CT has potential to improve treatment response assessment and overcome limitation of size based RECIST criteria.

PURPOSE

Decreased ADC derived by diffusion MRI has been the most widely accepted clinical imaging biomarker of tumor cellularity in various types of cancer. However, complex microenvironment surrounding tumor foci confounds ADC measurements sometimes failing to reflect tumor cellularity. We have developed a novel diffusion histology imaging (DHI) to characterize tissue structural changes resulting from various pathologies associated with solid tumors. DHI-derived restricted isotropic diffusion ameliorates confounding factors such as vasogenic edema, necrosis, and fibrotic structures, accurately assessing tumor cellularity quantifying signal fraction resulting from cellularity.

METHOD AND MATERIALS

Brain tumor specimens were examined using a 4.7T MR scanner with a homemade surface coil. Breast cancer and prostate cancer patients were examined on a 3T MR scanner with an 8-channel phased-array receive coil. DWI data with 99 (fixed specimens) or 25 (in vivo) diffusion encoding directions was processed using DHI multi-tensor modeling.

RESULTS

Decreased ADC in the adult anaplastic ependymoma (Fig. 1A) misidentified inflammation as tumors. In pediatric primitive neuroectodermal tumor (Fig. 1B), the ADC values of tumor did not consistently decrease as expected missing majority of histology-identified tumors. In contrast, DHI-restricted fraction map accurately delineated the H&E identified increase of tumor cellularity. In invasive ductal carcinoma, DHI more accurately identified increased cellularity revealed by H&E than ADC (Fig. 1C). In prostate cancer (Fig. 1D), ADC overestimated cancer lesion due to the coexisting BPH and inflammation. DHI correctly detected inflammation (highly-restricted isotropic diffusion), tumor (restricted isotropic diffusion), stromal BPH (anisotropic diffusion) and normal prostate tissues (non-restricted isotropic diffusion).

CONCLUSION

Despite its wide use in detecting increased cellularity associated with solid tumor growth, ADC is inconsistent to reflect tumor cellularity as demonstrated in various tumors as shown herein. DHI-restricted fraction accurately reflects tumor cellularity in adult and pediatric brain tumors, breast cancer, and prostate cancer.

CLINICAL RELEVANCE/APPLICATION

Our findings caution the continuing use of decreased ADC as the biomarker of increased tumor cellularity. We propose a better imaging method, such as DHI, more accurately detecting solid tumors will improve patient management.

PURPOSE

To assess the performance of an fully automated deep learning method in producing radiological gradings of spinal MRI in the context of management of chronic back pain

METHOD AND MATERIALS

A dataset comprising images of 12,018 individual discs from 2009 patients were retrospetively collected from 6 different referrral centers in the UK, Hungary, Slovenia and Italy in a previous EU project (Genodisc). The primary selection for recruitment to Genodisc was "patients who seek secondary care for their back pain or spinal problem" and were sourced from routine clinical management. The MRI machines and protocols varied between the sites but included at least one standard T2 sagittal MRI acquisition which, for consistency, was used for all of the results reported here, though the system is capable of using the T1 and axial images also. The scans were annotated with the following radiological scores by a single experienced spinal radiologist: Pfirrmann grade, disc narrowing, endplate defects, marrow changes, spondylolisthesis and central canal stenosis. To test the radiologist's intra-rater variability, they repeated their grading on a subset of 200 patients randomly interdispersed throughout the entire dataset. For training, the dataset was split into a 80:10:10 train:validation:test sets on a per patient basis (not per disc). This resulted in 1806 patients (10,836 discs) for training and 203 patients (1,224 discs) for testing. A multi-class Convolutional Neural Network (CNN) was trained using Deep Learning to predict all of the gradings. Accuracy was measured by comparing the output of the system to the radiologist annotations using class-balanced accuracy. Multi-way cross-validation was used to test the efficacy and repeatability of the system.

RESULTS

The average class balanced accuracy for the SpineNet system was 86.3% (+/- 0.3). This compares favourably to the radiologists intra-rater repeatability of 82.5%.

CONCLUSION

The SpineNet system can produce accurate and repeatable gradings for a range of spinal MRI radiological gradings used in chronic back-pain clinical management and research. Such gradings may be used to augment the radiologist report, improve consistency and communication with the referring physician.

CLINICAL RELEVANCE/APPLICATION

Quantitative gradings of spinal degeneration may be a useful adjunct to routine qualitative report of spinal MRI and improve communication with the referring phyician.

PURPOSE

To investigate the use of a deep learning (DL) approach to create a fully-automated prediction model for detecting anterior cruciate ligament (ACL) tears of the knee joint.

METHOD AND MATERIALS

The propsed deep learning approach consisted of two neural networks connected in a cascaded fashion to create a fully-automated processing pipeline. The first network performed rapid segmentation of the intercondylar notch on two to three consecutive image slices, while the second classification network evaluated structural abnormalities within the segmented anatomic region. Sagittal proton density-weighted fast spin-echo (PD-FSE) and fat-suppressed T2-weighted fast spin-echo (T2-FSE) sequences were acquired using the same 3T scanner on the knees of 200 subjects (100 subjects with a torn ACL and 100 subjects with an intact ACL at subsequently performed knee arthroscopy). The DL method was trained to detect ACL tears using both the PD-FSE and T2-FSE images on 100 randomly chosen subjects and evaluated on the remaining 100 subjects. Diagnostic performance of the DL method was assessed with receiver operation characteristic (ROC) and area under curve (AUC) analysis using arthroscopy as the reference standard. The diagnostic performance of a musculoskeletal radiology fellow and an experienced fellowship-trained musculoskeletal radiologist for detecting ACL tears in the same subject poulation was also calculated.

RESULTS

For the fellow and radiologist, the sensitivity (95%CI) for detecting ACL tears was 94% (81%-99%) and 97% (86%-100%) respectively, while the specificity (95%CI) was 98% (92%-100%) and 98% (92%-100%) respectively. In comparison, the sensitivity (95%CI) and specificity (95%CI) for the DL method for detecting ACL tears at the optimal threshold by the Youden index was 89% (74%-97%) and 98% (92%-100%) respectively. The AUC (95%CI) for the DL method was 0.942 (0.876-0.979, $p<0.001$), indicating high overall diagnostic performance.

CONCLUSION

A fully-automated DL approach showed high diagnostic performance for detecting surgically confirmed ACL tears, but its sensitivity was slightly lower than human readers indicating the need for larger training datasets to maximize diagnostic performance.

CLINICAL RELEVANCE/APPLICATION

A fully-automated DL approach trained on a small image dataset shows promise for detecting ACL tears but requires further optimization to achieve diagnostic performance comparable to human readers.

pchang077@gmail.com

PURPOSE

To evaluate a multi-step deep learning tool, based on convolutional neural networks (CNN), for fully-automated localization of vertebral bodies and detection of fracture on CT.

METHOD AND MATERIALS

After IRB approval, an institutional database was queried to identify patients with cervical, thoracic or lumbar CT obtained between January 2016 and 2017. For each patient, sagittal bone reconstructions were used to manually generate bounding cubes for each vertebral body. Additionally, all levels with a vertebral body fracture were identified. Final annotations were confirmed through visual inspection by a board-certified radiologist. A 3D mask R-CNN architecture based on a feature pyramid backbone was used to regress bounding cube locations for each vertebrae (Figure 1A). Subsequently, each vertebrae was cropped, resampled and used as input into a second 3D residual CNN for detection of fracture (Figure 1B). The 34-layer residual CNN architecture was implemented with bottleneck layers and all-convolutional design (no pooling). Performance was assessed on per vertebrae and per patient levels.

RESULTS

A total of 440 patients were included in this study, 88 of which had at least one vertebral body fracture. Overall, 174 of 3,206

individual levels contained a fracture. Accuracy, AUC, sensitivity, specificity, PPV and NPV were 0.961, 0.956, 0.845, 0.967, 0.590, 0.991 (per-vertebrae) and 0.859, 0.836, 0.875, 0.823, 0.558, 0.963 (per-patient). Combined, serial inference for the 3D mask R-CNN followed by the 3D residual CNN required 2.19 seconds per patient on a single GPU workstation.

CONCLUSION

A custom deep learning based tool is accurate for detection of vertebral body fracture. Given the potential subtle appearance of fractures and high resolution of CT spine imaging, a two-part serial architecture was required to integrate complimentary large field-of-view (vertebral body localization) and small field-of-view (fracture detection) information needed for this task.

CLINICAL RELEVANCE/APPLICATION

A high-performing deep learning tool for CT spine fracture detection can be used for rapid triage in the acute trauma setting, optimizing radiology workflow and expediting patient care.

SSG08-04 Automatic Detection of Distal Radius Fractures in X-Ray Images using Deep Learning

PURPOSE

The aim of this study was to evaluate the diagnostic performance of a multi-purpose, deep-learning based image analysis software for the detection of wrist fractures.

METHOD AND MATERIALS

In this retrospective study, patients with suspected wrist fractures on X-ray imaging studies ordered by the ER department between 2016 and 2017 were included. After applying exclusion criteria (e.g. presence of osteosynthesis material), the remaining X-ray images were labeled for the presence of radius fractures. In uncertain cases, CT studies were consulted, excluding cases missing CT confirmation. The cases were randomly split into training and test set (85% and 15%, respectively). A multi-purpose image analysis software was trained for the decision whether a distal radius fracture was present on the X-ray image. Training data was augmented (e.g. by horizontal flipping, shifting, rotating, scaling). The test set was subsequently processed by the trained system. Performance was measured as area under the ROC curve (AUC) from the score the software assigned to each image. Sensitivity and specificity were calculated at the optimal threshold as indicated by Youden's index. Finally, the test set was evaluated by an attending radiologist and a radiology resident with 16 and 2 years of experience, respectively.

RESULTS

The included images featured 171 cases with fractures and 562 controls, amounting to 733 X-ray images of 277 different patients. The training and evaluation set consisted of 573 and 160 X-ray images, respectively. The diagnostic performance of the trained software on the test set of 160 X-ray images was excellent with an AUC of 0.91 (95%-CI 0.85-0.95). It therefore performed comparable to a radiology resident (AUC 0.87, $p=0.25$) but worse than the attending radiologist (AUC 0.98, $p<0.01$). Sensitivity and specificity of the software at the optimal threshold were calculated to be 88.5% and 89.9%, respectively. Heatmaps drawn as an image overlay by the software indicated areas suspicious for defects as useful visual feedback. The interreader agreement of the human readers was substantial with a Cohen's kappa of 0.71 (95%-CI 0.60-0.82).

CONCLUSION

The software was able to detect wrist fractures with high sensitivity and specificity, using only a small dataset for training. It performed on a par with the radiology resident reader.

CLINICAL RELEVANCE/APPLICATION

Deep-learing based software is useful for the detection of wrist fractures.

PURPOSE

To develop and test a deep convolutional neural network (CNN) to automatically segment abdominal CT images for body composition measures. We hypothesized that a deep CNN would achieve high accuracy using a limited training dataset and data augmentation.

METHOD AND MATERIALS

We manually segmented single-slice CT images obtained at the level of L4 (80kV, 70mAs, 10mm slice thickness, 50cm field of view) in 160 subjects for determination of body composition. Manual segmentation was performed on 512x512 pixel images to label 6 classes: background, muscle, bone, bowel/solid organs, visceral and subcutaneous fat. Twenty cases were segregated for a test dataset. The remaining 140 underwent a processing pipeline of histogram equalization followed by data augmentation (N=2,000), which included random deformations, horizontal mirroring, Poisson noise, cropping and magnification. We trained our model from scratch on Keras/Tensorflow using an 80/20 training/validation split and a U-Net architecture (8 batch size, 50 epochs, dropout 0.3, initial learning rate 0.0001, softmax). Testing was performed to obtain the Dice (F1) score as a parameter to compare the similarity between manual vs. CNN-based multi-class segmentation.

RESULTS

The overall mean Dice score was 96% (median 97%, range, 94-98). Mean Dice scores for each class were: background 98% (median 98%, range, 96-99), bone 87% (86%, 83-92), subcutaneous fat 94% (96%, 87-98), muscle 91% (91%, 84-97), bowel/solid organs 89% (90%, 83-94), and visceral fat 81% (88%, 45-93). Visceral fat demonstrated the broadest accuracy range, which may derive from its more variable quantity and morphology, representing an important focus to improve algorithm performance.

CONCLUSION

Our results show overall accurate automated abdominal CT segmentation for body composition using a deep CNN algorithm, trained on a limited dataset with data augmentation. While segmentation accuracy was generally high for most classes (>81%), improvement of algorithm performance will focus on strategies to increase visceral fat segmentation accuracy. This workflow may serve as a basis for future models aimed at automated segmentation of entire abdominal CT studies for body composition.

CLINICAL RELEVANCE/APPLICATION

Deep CNN algorithms for tissue segmentation are promising methods to obtain body composition measurements, and may allow efficient and automatic data extraction in opportunistic and population studies.

SSG08-06 End to End Solution for Complete Thigh Muscle Semantic Segmentation from Musculoskeletal CT using Deep Learning

Tuesday, Nov. 27 11:20AM - 11:30AM Room: S102CD

N/A

PURPOSE

The goal is to develop and validate a 2.5D deep learning neural network (DLNN) to automatically classify thigh muscle into 10 classes and evaluate its classification accuracy over 2D DLNN.

METHOD AND MATERIALS

The clinical dataset consists of 48 thigh volume(TV) cropped from 24 anonymized non-contrast CT DICOM of lower extremities. Cropped volumes were aligned with femur axis and resample in 2mm voxel spacing. To reduce the annotation workload, final expert ground truth annotation was created by editing the predicted labels of muscle by a newly developed stacked U-Net DLNN. Stacked U-Net produces relatively higher segmentation accuracy on smaller muscles even when it is trained with small number annotated datasets. Proposed 2.5D DLNN consists of three 2D U-Net(optimizer: Adam, lr=1e-4,decay=1e-3) trained with axial, coronal and sagittal muscle slices respectively. A voting algorithm was used to combine the output of 2D U-Nets to create final segmentation. 2.5D U-Net was trained on PC(Intel Xeon 2.20GHz 128GB, NVIDIA Tesla P100-SXM2-16GB) with 38 TV(Epoch:100, Batch:32) and the remaining 10 TV were used to evaluate segmentation accuracy of 10 classes within Thigh. The result segmentation of both left and right thigh were de-cropped to original CT volume space. Finally, segmentation accuracies were compared between proposed DLNN and 2D U-Net(axial).

RESULTS

Average segmentation DSC score accuracy of all classes with 2.5D U-Net as 91.18% and Housdorff distance(HD) as 17mm. We found DSC score for 2D U-Net was 2.9% lower and HD was more than four times higher than the that of 2.5D U-Net.

CONCLUSION

Successfully implemented end-to-end solution for complete automatic classification with reasonable accuracy of thigh muscle into 10 classes . The same could be easily extend to muscle segmentation of any other body parts (lower limb, arm, shoulder etc.). To date, there is no other study of deep machine learning algorithm used except our study for CT based semantic muscle segmentation.

CLINICAL RELEVANCE/APPLICATION

Muscle segmentation functionality on PACS may improve visibility and can enable automatic quantitative evaluation of muscle atrophy with the disease progression. Change in volume or shapes of muscles will enable therapeutic interventions to be targeted to the affected regions only.

SSG08-07 A Deep-Learning System for Fully-Automated Muscle Assessment on Abdominal CT for Opportunistic Detection of Sarcopenia

jburns@uci.edu

PURPOSE

Central sarcopenia is a risk factor for mortality in multiple cancers, liver transplantation, cirrhosis, and trauma, and represents a topic of interest in multiple medical and surgical specialties to help guide patient management. We have created a fully-automated deep-learning system to opportunistically analyze truncal musculature for sarcopenia detection on CT scans obtained as part of the patient's routine clinical care

METHOD AND MATERIALS

First, individual lumbar vertebral bodies are segmented to separate bone from soft tissue, and create reference anatomic levels for muscle analysis, via thresholding, morphologic operations, and aggregated intensity profiles. Next, muscle groups at reference vertebral levels are segmented on axial images by a holistically nested neural network through image-to-image training and classification. There are varying reference level and muscle group standards for sarcopenia determination in different medical and surgical specialties. To accommodate this, the system performs analysis for multiple muscle groups and vertebral levels. Segmentation accuracy was assessed via Dice Similarity Coefficient, a measure of overlap between manual and automated segmentations. The system was trained on contrast enhanced portal venous phase CTs of 51 patients and tested on 51 cases (average age 67 (range 59-81), 53 F, 49 M). For demonstration here, the system was designed to calculate sarcopenia via the standard cutoff value for L3 SMI (skeletal muscle index: L3 axial muscle area cm2/patient ht m2) of < 3.62cm2/m2 for women and <4.93 cm2/m2 for men, as proposed by international consensus of cancer cachexia

RESULTS

The Dice coefficients for the psoas, paraspinous, and total abdominal muscle groups in the training and testing sets were 0.953 +/- 0.015 and 0.938 +/- 0.028, respectively at the level of the third lumbar vertebra. The mean normalized L3MI was 5.02 +/- 1.45 cm2/m2 for women and 6.18 +/- 1.83 cm2/m2 for men. Sarcopenia was present in 15.4% (8/52) of women and 13.3% (6/45) of men

CONCLUSION

This fully-automated system can robustly detect, accurately segment, and generate quantitative statistics for multiple abdominal wall muscle groups at multiple lumbar vertebral levels on CT scans

CLINICAL RELEVANCE/APPLICATION

Automated quantification of sarcopenia may guide patient management in pre-treatment risk assessment and surgical planning, and act as a platform to facilitate large scale clinical trials

SSG08-08 Machine-Learning-Based Discovery of Sexual Dimorphism of Hand and Wrist Radiographs

Tuesday, Nov. 27 11:40AM - 11:50AM Room: S102CD

sehyo.yune@mgh.harvard.edu

PURPOSE

Skeletal sexual dimorphism develops mostly in the pelvis during puberty. Although prior work has shown higher second-to-fourth digit ratio and smaller carpal bones in women compared to men, the distributions of these measures substantially overlap for women and men. We aim to create a machine-learning algorithm to distinguish sex from hand and wrist radiographs and evaluate its performance by comparing it to radiologists'.

METHOD AND MATERIALS

We compiled a dataset of 10,607 (5,148 male and 5,459 female) radiographs of hand and wrist from a cohort of patients, ranging from 5 years to 80 years of age. A total of 7,461 radiographs were used for training, and 1,573 images separate from the training data were randomly selected for validation. Images from the remaining 1,573 cases were reserved for testing. The images were labeled solely with the sex of the subject. We fine-tuned an ImageNet-pretrained VGG16 convolutional neural network (CNN) on our training dataset. The best CNN, selected based on the validation loss, then provided automated prediction of sex, which was compared to the sex in the medical record. To compare the performance with human radiologists, we randomly selected 50 cases for which the CNN correctly predicted sex. Two radiologists independently read the hand and wrist radiographs and predicted sex for these 50 cases. The radiologists were blinded to clinical information of the patients but were allowed to use reference such as the Greulich and Pyle atlas while reading the radiographs.

RESULTS

Of the 1,573 radiographs tested, the algorithm predicted sex correctly with 95.4% accuracy (95.2% in female and 95.7% in male).

The two radiologists showed 58% (45.8% in female and 69.2% in male) and 46% (50% in female and 57.7% in male) accuracy. The class activation maps (CAM) showed that the CNN mostly focused on 2nd and 3rd metacarpal base or 4th and 5th metacarpal head in women, and radioulnar/radiocarpal joint or 2nd, 3rd, and 4th metacarpophalangeal joints in men.

CONCLUSION

We developed an algorithm that accurately distinguishes men and women from hand and wrist radiographs in children as well as in adults.

CLINICAL RELEVANCE/APPLICATION

The current study shows the discovery of previously unrecognized radiologic features using machine learning. It could be used in screening of disorders affecting sexual development.

SSG08-09 Automated Radiograph Based Preoperative Measurements in FAI Patients Utilizing Deep Learning

Tuesday, Nov. 27 11:50AM - 12:00PM Room: S102CD

s.mutasa@columbia.edu

PURPOSE

Utilize deep learning to obtain preoperative measurements from radiographs in patients with femoroacetabular impingement.

METHOD AND MATERIALS

A retrospective study of patients with femoroacetabular impingement was performed. 181 unique patients who underwent CT scan of the hip for preoperative measurement of alpha angle (AA), acetabular version (AV), femoral version (FV) and lateral center edge (LCE) were identified. The training set consisted of 1084 radiographs. This was made up of available preoperative false profile, Dunn, frog leg and AP radiographs (n=419) and augmented with digitally reconstructed radiographs (DRRs) generated from the CT scans at different views (n=665). A novel convolutional neural network (CNN) based on a DenseNet architecture with 54 hidden layers and a regression head was trained on 256x256 input images to predict LCE measurement. For testing AA, AV, and FV measurements, both a regression output and a binary classifier for normal and abnormal ranges were tested. Parameters were tuned based on a 20% validation group generated from the training set. The sequestered testing set consisted of 95 preoperative radiographs at various views and corresponding measurements from accompanying CT scans.

RESULTS

Overall mean absolute error (MAE) and standard deviation of the error for LCE measurement was 3.2° ± 2.3°. Performance of the network was best on false profile views of the hip (3.0° ± 2.2°) but this difference was not statistically significant. AA, AV and FV prediction performance was evaluated, however the performance of the network was not predictive in the current implementation.

CONCLUSION

Deep learning techniques applied to radiographs can be used for quantitative measurement of LCE. With further modification and additional examples, quantitative measurement of AA, AV and FV may be possible.

CLINICAL RELEVANCE/APPLICATION

An accurate, automated system designed to obtain FAI measurements from radiographs can obviate the need for CT and has the potential to decrease healthcare costs, decrease patient exposure to radiation and increase radiologist efficiency.

PURPOSE

While PET perfusion imaging using dynamic acquisitions has a long history, its use in clinical practice outside of cardiovascular applications remains negligible. This Phase I study assesses the feasibility of dynamic PET perfusion imaging as an alternative methodology to contrast enhanced MRI in esophageal cancer using next-generation digital PET technology with substantially improved TOF timing resolution and reduced dead time.

METHOD AND MATERIALS

FDG PET/CT was performed prior to radiation therapy of advanced esophageal cancer in 12 patients using a next-generation digital photon counting system (Vereos Philips, dPET). Prior phantom and preclinical experiments established the following protocol. Dynamic PET Perfusion Imaging (DPPI) was performed at the time of bolus injection of 5 mCi FDG over a volume of interest for 10 min. PET events were recorded in continuous list mode acquisition and reconstructed using frame rates from 1 sec/fr to 15 sec/fr. A count density adaptive reconstruction approach was previously developed. Data analysis were performed using Intellispace Discovery (Philips) workspace. The reconstructed dynamic PET images were assessed in blinded review by three experienced PET readers. Descriptive statistics were calculated for data analysis.

RESULTS

All dynamic PET acquisitions were successfully acquired and reconstructed according to protocol. Frame rates of 10 sec led to high quality uptake time curves of the well delineated esophageal cancer. Count density adaptive reconstruction was essential to minimize noise. 2mm voxel length (HD) reconstruction was found to be beneficial. The first 2 min duration of the dynamic series were found to be the most relevant and also sufficient for the perfusion assessment. Uptake time curves were found analogous to characteristic findings in DCE-MRI.

CONCLUSION

Dynamic PET Perfusion Imaging (DPPI) of esophageal cancer was achievable using frame rates of 10 sec with acceptable quality for quantitative and visual assessment even at the low FDG dose of 5 mCi. A short table time of 5 min appears to be sufficient combined with the dPET's low dose capabilities making clinical utilization feasible.

CLINICAL RELEVANCE/APPLICATION

Dynamic PET perfusion imaging has the potential to be an alternative methodology to DCE-MRI or CT for assessment of perfusion of esophageal cancer for therapy planning and response assessment.

SSG09-02 Focal Liver Uptake on 18F-FDG PET/CT without CT Correlate: Utility of MRI Evaluation in Patients with Known Malignancy

PURPOSE

There is insufficient evidence to guide management of focal FDG uptake in the liver without CT correlate. This study aims to assess the utility of MRI for evaluation of focal FDG uptake on PET/CT without CT correlate in patients with known malignancy.

METHOD AND MATERIALS

In this IRB-approved, HIPAA compliant retrospective study, between 2005 and 2012, out of 1851 patients who underwent FDG-PET/CT, we identified 36 patients with known malignancy (19 women, 17 men; mean age, 56.1 years) who had focal hepatic uptake on PET/CT without CT correlate and had follow-up MRI within 100 days for assessment of the uptake. Two radiologists reviewed the PET/CT images in consensus blinded to the area of uptake noting SUVmax of the lesion and background liver. MR images were then reviewed to look for the presence of focal lesion corresponding to the uptake. When a focal lesion was present, the size, signal intensity and enhancement characteristics and follow-up imaging were documented. Statistical analysis was performed to determine correlation between intensity of FDG uptake and presence of focal lesion.

RESULTS

A total of 50 sites of focal hepatic uptake without CT correlate were identified. Median SUVmax was 4.1 (range 2.1-10.1) and median SUVmax ratio of hepatic lesion/normal parenchyma was 1.3 (range 0.98-2.6). MRI confirmed focal lesion in 26/50 sites (52%). Median lesion size was 13 mm (range 3-30 mm). Among 26 hepatic lesions noted on MR imaging, 77% (20/26) were diagnosed as metastatic disease (6 with pathological confirmation, 14 based on follow-up image findings). Other 6 lesions were diagnosed as benign, including 3 with pathological diagnosis of nodular regenerative hyperplasia (n=2) and heterogenous hepatic steatosis (n=1). There was no significant difference in the SUVmax of hepatic lesions (3.85 vs. 4.2, p=0.5) and the SUVmax ratio (1.32 vs. 1.31, p=0.97) between the groups with and without MRI correlate.

CONCLUSION

More than half of focal areas of uptake on PET/CT without CT correlate had a focal lesion on MRI in our study, and more than three-quarters of these MRI lesions were hepatic metastases, regardless of SUVmax values.

CLINICAL RELEVANCE/APPLICATION

In patients with known malignancy, focal FDG uptake in the liver without CT correlate warrants further assessment with MRI regardless of SUVmax as it is likely to be metastasis.

Philipp Heusch, MD, Duesseldorf, Germany (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To evaluate the impact of morphological information derived from contrast enhanced CT on the characterization of incidental, focal colonic uptake in 18F-fluordesoxyglucose positron emission tomography / computed tomography (18F-FDG PET/CT) examinations.

METHOD AND MATERIALS

In this retrospective study, 125 patients (female: n=53, male: n=72, mean age 62.9y) that underwent 18F-FDG PET/CT and colonoscopy (mean time between colonoscopy and PET: 52±58d) were included. By two readers, PET/CT examinations were assessed for incidental, focal colonic tracer uptake in comparison to the background. Focal tracer uptake was correlated with morphological changes of the colonic wall such as focal thickening, polypous shape or focal contrast media uptake. Discrepancies were resolved in a consensus reading. Then, colonoscopy reports were evaluated for precancerous (oligo-tubular adenoma, serrated adenoma, sessile adenoma and tubulo-villous adenoma) and cancerous lesions verified by histopathology, serving as a reference standard. Imaging findings were then compared to the reference standard to calculate sensitivity, specificity as well as positive (PPV) and negative predictive values (NPV) for focal tracer uptake in PET alone as well as focal tracer uptake in PET and

morphological changes in contrast enhanced CT in the detection of precancerous and cancerous lesions.

RESULTS

In 38.4% (48/125) of all patients, focal tracer uptake was observed in 67 lesions. In the corresponding colonoscopy reports, a total of 10 cancerous and 26 precancerous lesions were found. In PET, two cancerous lesions and 10 precancerous lesions were missed, resulting in a sensitivity, specificity, PPV and NPV of 51%, 68%, 29% and 84% for focal tracer uptake in PET alone. By correlation focal tracer uptake with morphological changes in contrast enhanced CT, a sensitivity, specificity, PPV and NPV of 48%; 79%; 37,5%; 86% for precancerous and cancerous lesions could be observed.

CONCLUSION

Focal colonic tracer uptake has a low specificity and sensitivity for precancerous and cancerous lesions. By analyzing additional morphological changes in contrast enhanced CT imaging in 18F-FDG PET/CT examinations, the specificity can be increased without sacrificing sensitivity.

CLINICAL RELEVANCE/APPLICATION

Morphological changes in 18F-FDG-PET/CT examinations help to decide, which patients with focal tracer uptake will profit from additional colonoscopy.

SSG09-04 Clinical Workflow of PET/MR for Primary Staging of Rectal Cancer

PURPOSE

analyze the clinical workflow of a PET/MR for rectal cancer staging, regarding MR imaging protocol, total scan time, prevalence and distribution of metastasis.

METHOD AND MATERIALS

55 patients with rectal adenocarcinoma were submitted to whole-body PET/MR for primary staging. MR sequences and total scan time were recorded. One reader analyzed the MR (blinded to PET findings) for locoregional staging. Another reader (blinded to the high-resolution MR of the pelvis) analyzed the PET/MR according to T, N and M staging. A third blinded reader analyzed only the liver MRI. Standard of reference was biopsy when feasible or imaging follow-up.

RESULTS

PET/MR workflow consisted of a dedicated pelvic MR, including high-resolution T2w and DWI, followed by whole-body PET/MR from head to mid thigh, ending with a T2w and DWI of the liver. Any dedicated MR sequence was used for the thorax. The mean total acquisition time of PET/MR was 64 minutes, ranging from 53 to 90 minutes. The PET acquisition time was on average 17 minutes, ranging from 12 to 25 minutes and the only-MR time was 52 minutes on average, including the dedicated pelvic and the liver sequences. One patient has not completed the exam due to claustrophoby and one patient was recalled due to low imaging quality (movement artifacts). For primary lesion detection, PET and DWI were positive in 54 out of 55 patients (one patient was negative even at MR). Metastatic disease was observed by PET/MR in 21 (38.2%) patients, mainly in the liver (12/21, 57.1%) non-regional lymph node (10/21, 47.6%), lungs (7/21, 33.3%) and peritoneum (1/21, 4.8%). Liver DWI detected 64 lesions in 12 patients and PET detected 62 lesions in the same 12 patients. Any brain metastasis was found.

CONCLUSION

PET/MR for rectal cancer staging is feasible, with a tolerable scan time and showing a high incidence of synchronic metastasis. DWI of the liver and of the rectum could be omitted in a staging/detection setting. PET coverage could start from skull base instead of vertex. Optimization of MR protocol would decrease scan time and allow the inclusion of other MR sequences.

CLINICAL RELEVANCE/APPLICATION

PET/MR for rectal cancer may be used clinically as a one-stop-shop imaging tool for whole-body staging.

SSG09-05 PET/MR for Staging Rectal Cancer: A Comparison to Conventional Staging with Pelvic MR and Thoracoabdominal CT

marcelo.queiroz@hc.fm.usp.br

PURPOSE

To compare the detection rate of metastatic lesions on PET/MR versus conventional staging (pelvic MR and thoracoabdominal CT) in rectal cancer patients referred for primary staging.

METHOD AND MATERIALS

Ninety-five patients with biopsy proven rectal adenocarcinoma were submitted to whole-body PET/MR for primary staging in addition to conventional staging with pelvic MR and thoracoabdominal contrast-enhanced CT (ceCT). One reader analyzed the MR (blinded to PET findings) regarding locoregional staging. Another reader (also blinded to the high-resolution part of pelvic MR) analyzed the PET/MR about T-, N- and M-stage. A third blinded reader assessed the M-stage by ceCT. Standard of reference was biopsy when feasible or imaging follow-up. Lesions were cateogrized as positive, negative or indeterminate.

RESULTS

On a lesion-based analysis, PET/MR detected 24.5% more positive metastatic lesions than conventional imaging (305 vs. 254 lesions). The higher detection rate on PET/MR was observed for non-regional lymph nodes (73 vs. 37 lesions). On a patient-based, PET/MR was positive in 38 out of 95 patients (40%), while conventional staging in 24 out of 95 patients (25.3%). PET/MR was indeterminate in 7 patients (7.4%), which 1 was positive on CT (non-regional lymph nodes, later confirmed to be sarcoidosis), while conventional imaging was in 30 patients (31.6%), which 10 were positive on PET/MR, mainly for non-regional lymph nodes and liver.

CONCLUSION

For rectal cancer staging, PET/MR presents not only a higher detection rate of metastatic lesions than conventional imaging (pelvic MR and thoracoabdominal ceCT), but also clarifies the etiology indeterminate lesions.

CLINICAL RELEVANCE/APPLICATION

PET/MR might be preferred for whole-body staging of rectal cancer patients, with a higher detection rate and potential clinical impact.

SSG09-06 Diagnostic Performance of PET/MR in Identifying High-Risk Primary Rectal Cancer Patients

Tuesday, Nov. 27 11:20AM - 11:30AM Room: S505AB

PURPOSE

to assess the diagnostic performance of PET and MR parameters to identify high-risk rectal cancer patients.

METHOD AND MATERIALS

fifty-three patients with biopsy proven rectal adenocarcinoma were submitted to whole-body PET/MR for primary staging. One reader analyzed the MR (blinded to PET findings) regarding T stage, mesorectal fascia involvement, extramural vascular invasion, and presence of locoregiona nodal disease. Another reader (also blinded to the high-resolution part of pelvic MR) measured the semiquantitative PET parameters using a dedicated software (PETVCAR, GE Healthcare) and assessed the M stage. Standard of reference was biopsy when feasible or imaging follow-up. Mann-Whitney test was performed to compare PET parameters between high and low-risk patients. ROC analysis was also used to define the diagnostic perfomance of PET parameters in identifying the tumor risk.

RESULTS

PET-volumetric parameters, namely TLG and MTV, performed better than SUVmax and mean to distinguish low and high-risk patients. MTV (48.9 vs. 18.4, $p = 0.006$) and TLG (629.4 vs. 190.4, $p = 0.008$), but not SUVmax (23.4 vs. 19.2, $p = 0.306$) or SUVmean (11.7 vs. 9.9, $p = 0.285$) were significantly higher in high-risk patients. Patients with advanced T stage, positive regional node and metastatic disease also presented significantly higher MTV and TLG values. No difference was found in any PET parameters in patients according to the involvement of mesorectal fascia and presence of EMVI. The AUC to distinguish low and high-risk patients was 77.9% ($p = 0.006$) for MTV and 77.0% ($p = 0.008$) for TLG and the best cut-off value (sensitivity of 83.7% and specificity of 70%) of MTV and TLG to detect high-risk patients was 16.1 and 172.8, respectively.

CONCLUSION

In addition to MR adverse risk factors, the volumetric-based PET parameters (MTV and TLG) allow the identification of high-risk patients, which could tailor therapy management.

CLINICAL RELEVANCE/APPLICATION

PET/MR provides morphologic and metabolic parameters to identify high-risk rectal cancer patients that need more detailed staging in a whole-body setting. The volumetric-based PET parameters (MTV and/or TLG) might be included in clinical reports instead of SUVmax.

SSG09-07 PET/MR Characterization of Mucinous versus Nonmucinous Components of Rectal Adenocarcinoma: A Comparison of Tumor Metabolism and Cellularity

PURPOSE

to analyze the relation of mucinous component of rectal adenocarcinoma to FDG avidity and diffusion restriction.

METHOD AND MATERIALS

ninety-four patients with biopsy proven rectal adenocarcinoma were submitted to whole-body PET/MR for primary staging. One reader analyzed the MR (blinded to PET findings) regarding locoregional staging, including the presence of mucinous component. Another reader (also blinded to the high-resolution part of pelvic MR) analyzed the PET/MR according to T, N and M staging. Two different readers drawn in consensus the volume of interest (VOI) larger than 0.5 cmCubed of the mucinous component (MC) and the non-mucinous component (NMC) of the primary tumor on high-resolution T2w sequence and propagated the VOI to PET, DWI and ADC. SUVmax, SUVmean, TLG, MTV, ADCmax, ADCmean and ADCmin values were recorded and compared using Mann-Whitney test.

RESULTS

Seventeen patients (18.1%) presented MC on MRI. The SUVmax and SUVmean of the NMC were significantly higher than of the MC (16.7 vs. 7.4, p = 0.002 and 13.4 vs. 5.4, p = 0.001). Any of the ADC values was significantly different between MC and NMC groups.. Among the 17 patients with MC, 16 (94.1%) were at least mrT3b, 15 (88.2%) presented positive extramural vascular invasion, 14 (82.4%) had involvement of mesorectal fascia, 13 (76.5%) were N-positive and 8 (47.1%) presented distant metastasis, reinforcing the correlation of MC and tumor risk.

CONCLUSION

The MC identified on PET/MR presents lower glycolytic metabolism than the NMC and is associated with high tumor risk. Tumor cellularity was not different between MC and NMC.

CLINICAL RELEVANCE/APPLICATION

PET/MR enables a conspicuous correlation of mucinous component and tumor metabolism. Imaging readers should be aware of this pattern, recognizing that both primary and metastatic disease of mucinous tumors present low FDG uptake.

SSG09-08 Comparative Accuracy of Qualitative and Quantitative 18F-FDG PET/CT Analysis in Detection of Lymph Node Metastasis from Anal Cancer

PURPOSE

To evaluate the diagnostic performance of qualitative and quantitative FDG PET combined with CT in detection of regional and distant lymph node metastases in patients with anal cancer

METHOD AND MATERIALS

In this IRB approved retrospective study between January 2000 and December 2017, a total of 29 patients (F/M;17/12), mean age 59.9±13.7 (15-95) with anal cancer who had staging PET/CT and pathological analysis of suspicious lymph nodes were included for qualitative and quantitative analysis. For qualitative analysis, the positive lymph nodes were defined as uptake close to or higher than the liver background. For quantitative study, lymph nodes were contoured using the 3D region of interest (ROI) to determine

the maximum standard uptake value (SUVmax) and metabolic tumor volume (MTV). Receiver operating characteristic (ROC) curves were analyzed to extract the optimal cut-off values of SUVmax, lesion to background (L/B) ratio, short axis diameter (SAD) and MTV of the lymph nodes. Histopathologic analysis was the reference standard.

RESULTS

A total of 29 lymph nodes (25 inguinal, 2 external iliac, 1 internal iliac and 1 paraaortic nodes) in 29 patients on PET/CT were included for analysis. For qualitative visual analysis, PET/CT interpreted 27 patients as positive for the presence of nodal metastases with sensitivity, specificity and accuracy of 1, 0.25 and 0.79. The optimal cut-off values of SUVmax and L/B ratio were 2.51 and 1.13 with sensitivity and specificity of 0.91, 0.75 and area under the ROC curve (AUC) of 0.863 (95%CI:0.685,0.962) for SUVmax and 0.887 (95%CI:0.714,0.974) for L/B ratio. Using a best discriminative cut-off value 1.5 cm for SAD and 3.53 cm3 for MTV, the sensitivity and specificity were 0.81 and 1 with AUC of 0.952 (95%CI:0.803,0.997) for SAD and 0.935 (95% CI:0.777,0.993) for MTV. If we used the optimal cut-off value of either SUVmax or SAD, the sensitivity will increase to 0.95 (95%CI:0.76,0.99) with a specificity of 0.75 (95%CI:0.35,0.97).

CONCLUSION

Quantitative analysis of lymph node metastases in patients with anal cancer obtained with SUVmax, L/B ratio, nodal size and MTV are more specific and accurate than those performed with qualitative analysis but slightly less sensitive.

CLINICAL RELEVANCE/APPLICATION

The presence of nodal metastasis is crucial for treatment planning. Inguinal nodes with gross nodal involvement will receive a booster dose. Distant metastasis will change the chemotherapy regimen.

SSG09-09 68Ga-DOTATATE PET/CT as a Predictive Marker for 177Lu-DOTATATE Therapy

PURPOSE

Lutetium-177 (177Lu)-DOTATATE has shown significant promise in patients with somatostatin receptor positive neuroendocrine tumors (NETs). Here we report our preliminary experience with the use of 68Ga-DOTATATE PET/CT as a predictive marker for outcomes with 177Lu-DOTATATE therapy.

METHOD AND MATERIALS

Fifteen patients with progressive metastatic NETs were enrolled at our institution on the Expanded Access Program for 177Lu-DOTATATE. Pre-treatment 68Ga-DOTATATE PET/CT scans were performed in all patients. A retrospective analysis of these PET/CT scans was performed for tumor burden. Indices measured include maximal SUV uptake (SUVmax) and total SUV uptake (SUVtotal), which is the sum of 68Ga-DOTATATE uptake by all the lesions in one patient's PET scan. Tumor burden is the sum of all tumor volumes. These measurements were correlated with progression-free survival.

RESULTS

Of the 15 enrolled patients, six completed all four 177Lu-DOTATATE infusions, and 9 patients completed 3 or fewer infusions. Median progression-free survival is 80% at 12 months from the date of enrollment. The pre-treatment 68Ga-DOTATATE PET/CT demonstrated well-differentiated NETs and wide-spread metastases in all 15 patients, with liver, lymph nodes and bone being the most common sites. Our data showed a larger tumor burden (1824 ml vs. 748 ml) and higher SUVtotal (636 thousand vs. 186 thousand) in deceased patients vs. patients with stable disease, while SUVmax had the opposite trend (36.5 vs. 51.0).

CONCLUSION

It may be possible to metrics from the pre-therapy 68Ga-DOTATATE PET/CT to predict outcomes of 177Lu-DOTATATE in patients with metastatic NET. While the results are encouraging, larger cohorts are needed to establish 68Ga-DOTATATE PET/CT based predictive factors for progression-free survival.

CLINICAL RELEVANCE/APPLICATION

68Ga-DOTATATE PET/CT could serve as a clinical predictor for response to 177Lu-DOTATATE.

PURPOSE

Diagnosis of pseudoprogression (PsP) is a challenging issue for glioblastoma patients in their early post-treatment state. We developed a multiparametric radiomics model using diffusion- and perfusion-weighted MRI and externally validated to facilitate the diagnosis.

METHOD AND MATERIALS

Patients with glioblastomas within 3 months followed by Stupp protocols were reviewed and 61 consecutive patients exhibiting enlarging contrast enhancing masses on MRI were enrolled (PsP = 26). 6472 multiparametric radiomic features were extracted from post-contrast T1-weighted, FLAIR images, ADC and CBV maps. Imaging features were selected using the least absolute shrinkage and selection operator logistic regression model and redundant features were removed. The performance of radiomics model was calculated using the area under the receiver operating characteristics curve (AUROC) and compared with histogram parameters of ADC (ADC10) and CBV (CBV90). To improve validity, the multiparametric radiomics model was tested in an external data set with histopathologic confirmation (n = 34).

RESULTS

Twelve significant radiomic features (1 from post-contrast T1-weighted, 2 from FLAIR, 2 from ADC, and 7 from CBV maps) were selected to construct the radiomics model. The multiparametric radiomics model (AUROC 0.90, 95% confidence interval [CI] 0.82-0.98) showed significantly better diagnostic performance of pseudoprogression than any single parameter of ADC10 (AUROC 0.70, CI 0.46-0.76) or CBV90 (AUROC 0.61, CI 0.66-0.88), and outperformed than a conventional radiomics model using post-contrast T1-weighted and FLAIR only (AUROC 0.76, CI 0.63-0.88). The multiparametric radiomics model also showed better diagnostic performance in the external validation (AUROC 0.85, CI 0.71, 0.99) than single parameters (AUROC 0.43-0.50) and a conventional radiomics model (AUROC 0.74, CI 0.67-0.97).

CONCLUSION

The multiparametric radiomics model improved diagnostic performance for diagnosing pseudoprogression in glioblastoma patients in their early post-treatment state and showed robustness in multi-center setting.

CLINICAL RELEVANCE/APPLICATION

Pseudoprogression is a diagnostic challenge in neuroradiology, especially in their early post-treatment state of less than 3 months followed by Stupp protocols for glioblastoma patients. Multiparametric radiomics model has good generalizability with improved diagnostic performance, which augments the role of diffusion and perfusion MRI.

SSG10-02 Immune Checkpoint Inhibitors Against Glioblastoma: Imaging Assessment of Therapy Response

Tuesday, Nov. 27 10:40AM - 10:50AM Room: E353A

Participants
Javier Villanueva-Meyer, MD, San Francisco, CA (*Abstract Co-Author*) Nothing to Disclose
Tyler J. Gleason, MD, San Francisco, CA (*Presenter*) Nothing to Disclose
Nancy Ann Oberheim Bush, San Francisco, CA (*Abstract Co-Author*) Nothing to Disclose
Tarik Tihan, San Francisco, CA (*Abstract Co-Author*) Nothing to Disclose
Soonmee Cha, MD, San Francisco, CA (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

Immunotherapeutic strategies are increasingly pursued as upfront and salvage therapies in glioblastoma. Early results with vaccine trials have shown a subset of patients achieve radiographic response, develop stable disease, or have enhanced survival despite early worsening of imaging findings. Here, we assess the imaging findings and outcomes in a cohort of glioblastoma patients treated with immune checkpoint inhibitors.

METHOD AND MATERIALS

We analyzed MR imaging from twenty-nine patients with newly-diagnosed or recurrent glioblastoma treated with immune checkpoint inhibitors. Morphologic and physiologic MR imaging characteristics including diffusion and perfusion imaging were evaluated and clinical outcomes were assessed. Relevant histopathology from sampled tissue was also evaluated.

RESULTS

The majority (20, 69%) of patients on immune checkpoint inhibitors developed early radiographic progression of disease within six months of starting therapy. Of those, seventeen (59%) developed definitive progressive disease radiographically or clinically at follow-up. Eight patients underwent re-resection with pathologic confirmation of progression or treatment related changes. Progressive disease was related to increasing volume of FLAIR signal abnormality, decreased normalized apparent diffusion coefficient, and increased cerebral blood flow ($p<0.05$). Patients with recurrent glioblastoma developed marked early progression with significantly shorter progression free survival compared to newly diagnosed glioblastoma ($p=0.02$). While commonly observed imaging patterns of progression included disseminated leptomeningeal and subependymal disease, particularly in cortex and subventricular zone positive tumors, no significant survival difference was found when stratifying by tumor location.

CONCLUSION

In this retrospective study, glioblastoma treated with immune checkpoint inhibitors was often found to demonstrate early radiographic progression of disease with unique patterns of progression. These findings provide an initial insight into the imaging of glioblastoma treated with immune checkpoint inhibitors and highlight the role of imaging in patient selection and therapeutic response assessment.

CLINICAL RELEVANCE/APPLICATION

Immunotherapy is expected to play an ever-expanding role in glioblastoma treatment. Familiarity with radiographic findings following immunotherapy for glioblastoma is paramount for patient care.

SSG10-03 Virtual and Augmented Reality Helps in Pre-Operative Planning of Brain Tumors

vakumar@mdanderson.org

PURPOSE

To compare virtual reality (VR) and augmented reality (AR) in the pre-operative planning of complex glioma cases.

METHOD AND MATERIALS

After obtaining IRB approval, the clinical MRI exams of 1,250 cases of adult cerebral hemispheric gliomas of all histologic types were examined and characterized. Complex cases were evaluated in 3D with VR and AR using Anatom-e (Houston, TX).

RESULTS

We found that VR which works with a computer screen and a headset in a closed 'purely virtual' environment is a robust technology. It was helpful in pre-operative planning,which included mapping out the gyral anatomy, arteries, veins, as well as tumor infiltration patterns. However, at this time, this technology can only be used by a single user. AR technology is rapidly evolving. AR uses a clear goggle system which allows the user to see his/her 'real' environment and overlays holographic images onto the patients MR imaging. When used, we found AR was superior to VR in anatomy and tumor display. AR is also capable of being shared by multiple viewers, which is of value in communicating with the surgeon and consultation with other colleagues in real time. However, AR is currently not stable enough for consistent use in clinical cases. AR has the potential to be used intraoperatively, by fusing holographic images to the patient's own brain during surgery.

CONCLUSION

Both VR and AR are innovative alternatives to analyse complex glioma cases for pre-operative planning. At this time, VR is superior to AR, as it is better established and a stable platform. However, as technology advances, AR will likely overtake VR for pre-operative planning of brain tumors.

CLINICAL RELEVANCE/APPLICATION

Continued development of technologies such as VR and AR are needed to advance neuroimaging and surgical planning.

SSG10-04 Simultaneous Permeability Measurements Using Dynamic Susceptibility Contrast Imaging Enhances Differential Diagnosis of Primary Central Nervous System Lymphoma from Glioblastoma

Tuesday, Nov. 27 11:00AM - 11:10AM Room: E353A

peachwh@naver.com

PURPOSE

Simultaneous perfusion and permeability measurements become feasible with tissue-residue function based leakage correction in dynamic susceptibility contrast MRI (DSC MRI). We aimed to test whether estimates of adding permeability parameters obtained from single short acquisition of DSC-MRI improves diagnostic performance for distinguishing primary central nervous system lymphoma (PCNSL) from glioblastomas.

METHOD AND MATERIALS

This retrospective study was approved by the institutional review board. Total 145 patients with pathologically proven glioblastomas (n=89) and PCNSL (n=56) were enrolled. Two post-processing methods were used to calculate leakage corrected cerebral blood volume (CBV), using Weisskoff-Boxerman method (normalized CBV, nCBV) and tissue residue function-based method (CBVres). Vascular permeability parameter of extraction fraction (EF) was further calculated with the latter. Diagnostic performance to distinguish PCNSL from glioblastoma was calculated for CBVs and adding EF, using the area-under-the curve from the receiver operating characteristics curve (AUROC) and cross-validated with boot-strapping.

RESULTS

PCNSL demonstrated significantly higher EF (10.49 ± 6.89 %) and lower CBVs (nCBV, 3.13 ± 1.33; CBVres 3.23±2.51 relative units) compared to glioblastoma (EF, 4.30 ± 2.4 %; nCBV, 6.01 ± 4.1; CBVres, 6.45 ± 3.54 relative units, $P < .001$). Combined perfusion and permeability measurements significantly improved diagnostic performance (AUROC, 0.89; 95% confidence interval 0.84-0.94) to any single parameter of nCBV (AUROC 0.78, 0.71- 0.85, $P = 0.02$) and CBVres (AUROC 0.80, 0.73-0.86, $P<0.001$), and performed better than EF (AUROC 0.83, 0.75-0.86).

CONCLUSION

Simultaneous perfusion and permeability measurement on single DSC MRI acquisition improved diagnostic performance in differentiating PCNSL from glioblastoma.

CLINICAL RELEVANCE/APPLICATION

Obtaining permeability parameters for brain tumor evaluation requires double gadolinium contrast injection, long imaging acquisition time and complex post-processing methods. Our results suggests that simultaneous perfusion and permeability parameters derived from a single DSC-MRI acquisition provided useful biomarker and improved diagnosis for differentiating PCNSL from glioblastomas.

SSG10-05 Arterial Spin Labeling for Glioma Grade Discrimination: Correlations with IDH1 Genotype and 1p/19q Status

Tuesday, Nov. 27 11:10AM - 11:20AM Room: E353A

Participants
Ning Wang, Guangzhou, China (*Presenter*) Nothing to Disclose
Weidong Zhang, MD, PhD, Guangzhou, China (*Abstract Co-Author*) Nothing to Disclose

For information about this presentation, contact:

wangning@sysucc.org.cn

PURPOSE

To evaluate the diagnostic efficacy of perfusion values derived from arterial spin labeling (ASL) to grade gliomas. In addition, the correlation between perfusion parameters and isocitrate dehydrogenase 1 (IDH1) genotypes and 1p/19q status of gliomas were assessed.

METHOD AND MATERIALS

The institutional review board approved this retrospective study. From October 2015 to January 2018, a total of 53 cases of supratentorial gliomas in adults who received ASL magnetic resonance imaging were included. The cerebral blood flow (CBF) images derived from ASL and the anatomical maps were normalized to the Montreal Neurological Institute coordinate system and then matched. Both qualitative and quantitative analyses of CBF were performed. The mean and maximum CBF were obtained from the whole solid part and the largest perfusion area of the tumor, respectively. The relative values were calculated by dividing the CBF value of the contralateral grey matter area. The pathological results were diagnosed according to the 2016 WHO criteria.

RESULTS

Perfusion in the high-grade group was significantly higher than that in the low-grade group. The maximum CBF, the relative mean

CBF, and the maximum CBF, all showed statistical differences between the low and high-grade groups. Among all the parameters, relative maximum CBF showed the best diagnostic efficacy, with a cutoff value of 1.59, which yielded a sensitivity and specificity of 81% and 75%, respectively. The CBF qualitative analysis showed that the IDH1 mutant group tended to have lower perfusion than the IDH1 wild-type group, with a Phi and Cramer's V coefficient of 0.266. In the sample containing only diffuse astrocytoma, anaplastic astrocytoma, and glioblastoma, the relative mean and maximum CBF were significantly different between the IDH1 mutant and wild-type groups, and correlation analysis found that the Phi and Cramer's V coefficient was 0.395. There was no significant association between 1p/19q codeletion and the perfusion parameters.

CONCLUSION

ASL can offer accurate perfusion values to grade gliomas. There was a mild correlation between IDH1 genotypes and perfusion, and no significant association between 1p/19q status and perfusion of gliomas.

CLINICAL RELEVANCE/APPLICATION

The association between perfusion values from ASL and pathological grades and genotypes of gliomas might enhance the role of MR imaging in the clinical management and prognostic evaluation of gliomas.

SSG10-06 Diagnostic Performance of 2-hydroxyglutarate Magnetic Resonance Spectroscopy for Prediction of Isocitrate Dehydrogenase (IDH) Mutant Glioma: A Systemic Review and Meta-Analysis

Tuesday, Nov. 27 11:20AM - 11:30AM Room: E353A

Participants
Chong Hyun Suh, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose
Ho Sung Kim, Seoul, Korea, Republic Of (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

We aimed to investigate the diagnostic performance of 2-hydroxyglutarate (2HG) magnetic resonance spectroscopy (MRS) for prediction of isocitrate dehydrogenase (IDH) mutant glioma.

METHOD AND MATERIALS

A systematic literature search of Ovid-MEDLINE and EMBASE was performed to identify original articles investigating the diagnostic performance of 2HG MRS for prediction of IDH mutant glioma up to March 20th, 2018. The pooled sensitivity and pooled specificity and their 95% CIs were calculated using a bivariate random-effects model and the coupled forest plot was obtained. Meta-regression was performed to explain the effects of heterogeneity.

RESULTS

Fourteen original articles in a total of 460 patients were included. IDH mutant gliomas consistently showed a significantly higher accumulation of 2HG compared to IDH wild-type gliomas. The pooled sensitivity and specificity for the diagnostic performance of 2HG MRS for prediction of IDH mutant glioma were 95% (95% CI, 85-98%) and 91% (95% CI, 83-96%), respectively. The area under the HSROC curve was 0.96 (95% CI, 0.94-0.98), which suggests high diagnostic performance. The Higgins I2 statistic demonstrated that heterogeneity was present in the sensitivity (I2 = 50.69%) whereas no heterogeneity was noted in the specificity (I2 = 30.37%). In meta-regression, MRS sequence and TE were associated with study heterogeneity. Among the studies using PRESS, studies using long TE (97 ms) showed higher sensitivity (92% [95% CI, 85-99%]) and specificity (97% [95% CI, 92-100%]) compared to studies using short TE (30-35 ms) (sensitivity of 90% [95% CI, 79-100%], specificity of 88% [95% CI, 83-93%]) ($p < 0.01$).

CONCLUSION

2HG MRS demonstrated excellent diagnostic performance for prediction of IDH mutant glioma

CLINICAL RELEVANCE/APPLICATION

Further validation and applying 2HG MRS to daily practice would be critical in glioma management.

SSG10-07 Preoperative Determination of Isocitrate Dehydrogenase Mutation in Gliomas Using Multiparametric MRI

thnguyen@toh.on.ca

PURPOSE

To predict preoperatively IDH1 mutant status in gliomas using a multiiparametric approach based on tumor volume, presence of 2-hydroxyglutarate (2-HG), dynamic contrast-enhanced (DCE) and intravoxel-incoherant motion(IVIM) derived parameters.

METHOD AND MATERIALS

Patients with a suspicion of a glioma were prospectively enrolled before surgical resection. Each patient underwent a conventional MR examination with the addition of a spectral editing MRS (MEGA-PRESS), DCE-MR and IVIM. Parameters for the MEGA-PRESS sequence were: TR=2000ms, TE=60ms, 64 acquistions, voxel size=8cm3, duration=4.5min. 2-HG of the substracted MEGA-PRESS spectra was analyzed using jMRUI v5.2. ROIs were manually drawn around the whole tumour volumes on conventional MR images and superimposed onto the IVIM and DCE-derived parametric maps to measure volume transfer constant (Ktrans), fractional volume of blood plasma in tissue (Vp), apparent diffusion coefficient (D), pseudodiffusion coefficient (D*), and perfusion fraction(f). Sensitivity and specificity for the prediction of IDH status were calculated using immunohistochemistry as the gold standard.

RESULTS

A total of 45 patients were enrolled: 10 patients with IDH+ gliomas (4 Grade II, 6 Grade III); 35 patients with IDH- gliomas (1 Grade I, 5 Grade III, 29 Grade IV). IDH+ gliomas showed lower enhancing and necrotic volumes but higher non-enhancing volumes. IDH+ gliomas had lower values for Ktrans and Vp. There was no statistically significant difference in the IVIM parameters between the two groups. For differentitation between IDH- and IDH+ gliomas, sensitivity and specificity were 33% and 95% respectively for 2-HG measured from MRS, 89% and 71% respectively from enhancing tumour volume using a cut-off<3640mm3, 89% and 93% for mean Ktrans using a cut-off<0.004min-1, 89% and 64% for mean Vp using a cut-off<0.083%.

CONCLUSION

IDH+ gliomas showed higher non-enhancing tumour volume and lower Ktrans and Vp than IDH- gliomas. The majority of our patients were high grade gliomas, which are less likely to be IDH+. This may have led to the finding that IDH-tumours appeared to have higher vascularity.

CLINICAL RELEVANCE/APPLICATION

IDH status in patients with suspected gliomas can be predicted preoperatively using a multiparametric method combining conventional MRI, MRS and perfusion imaging.

SSG10-08 Glioblastoma versus Cerebral Metastases: Differentiation Using a Radiomic Evaluation on Post-Contrast 3DT1 MR Images

PURPOSE

To evaluate the diagnostic performance of magnetic resonance (MR) texture analysis in differentiating glioblastoma (GBM) from cerebral metastases (MET) on post-contrast 3 dimensional T1 weighted sequences (3DT1).

METHOD AND MATERIALS

140 patients (70 individuals with GBM > 2cm diagnosed between January 2013 and March 2018 and 70 with cerebral MET > 2cm diagnosed between August 2010 and March 2018) were enrolled in this retrospective bicentric study. All patients had post-contrast 3DT1 sequence acquired on 3T MRI (GE Discovery 750w) with the same protocol. Segmentation of all tumoral lesions was performed semi-automatically on Olea Medical software and 42 radiomic features were computed using LIFEx freeware. As a part of radiomics analysis, texture analysis is a method of extracting quantitative features that evaluate specifically the spatial arrangement of gray levels in a volume to obtain more information about tumor heterogeneity. Patients were separated in training and validation sets for statistical analysis. Univariate analysis was first performed to select the most informative radiomic features. A multivariate regression was then realized to construct and validate a model predicting lesion type. Area under ROC curves (AUC) and p-values from Wilcoxon's test were calculated to evaluate the performance of each classifier.

RESULTS

According to univariate analysis realized on the training set (GBM: N = 46, MET: N = 46), 6 textural features were statistically significant (p<0.00001, for 3 features; p<0.001, for 3 features). The mean AUC of the multivariate radiomics classifier combining 3 textural features from gray level zone-length and co-occurrence matrices was 0.854 (95% CI 0.77-0.93). These results are to be confirmed on the validation set which is still in process.

CONCLUSION

Texture analysis on post-contrast 3DT1 MR images is useful to differentiate cerebral MET and GBM. The implementation of this method for automatic characterization of tumoral lesions in clinical software would have a strong impact in the management of patients.

CLINICAL RELEVANCE/APPLICATION

Glioblastoma and cerebral metastases are the most frequent malignant brain tumors. Texture analysis is an objective tool to differentiate these 2 diseases which have different therapeutic strategies.

SSG10-09 Deep Learning-Based Analysis of Quantitative MRI Features to Identify IDH-Mutant Glioblastoma Multiform

Tuesday, Nov. 27 11:50AM - 12:00PM Room: E353A

PURPOSE

Glioblastoma multiforme (GBM) is the most common primary brain tumor in adults and carries a poor prognosis with a median survival of less than 2 years. Recent studies have shown that GBMs harboring mutations in isocitrate dehydrogenase (IDH) are associated with improved survival, and may benefit from maximal resection including the non-enhancing tumor component. Unfortunately, IDH status is sometimes only available after resection. The purpose of this study is to evaluate quantitative MRI based imaging features that can be used to identify IDH-mutant GBMs on preoperative imaging.

METHOD AND MATERIALS

We analyzed preoperative MR images from 13 patients with pathologically proven IDH-mutant GBMs and 99 patients with IDH-wildtype GBMs. The MRI protocol included T1, T2, FLAIR, and post-contrast T1 images, in addition to 55-direction diffusion tensor imaging. A convolutional neural network-based deep learning algorithm was used to generate automated volumetric segmentation of the three key components of GBM that are seen on MRI: enhancing tumor core, non-enhancing tumor, and necrosis. Tumor compartment volume fractions and DTI parameter values were compared between IDH-mutant and wildtype GBMs.

RESULTS

IDH-mutant GBMs demonstrated lower enhancing tumor fraction compared to wildtype GBMs, as well as lower volume ratios of enhancing to non-enhancing tumor and enhancing tumor to necrosis ($p < 0.05$ with Bonferroni correction). IDH-mutant GBMs also had higher average apparent diffusion coefficient within the necrotic region, consistent with the clinical observation that these tumors often have heterogeneous and/or cystic non-enhancing components; however, this difference was not significant after Bonferroni correction.

CONCLUSION

In this small retrospective study, IDH-mutant GBMs demonstrated statistically significant differences in enhancing tumor fraction compared to IDH-wildtype GBMs. These findings are in line with the theory that IDH-mutant GBMs represent secondary GBMs that develop from lower grade gliomas. Our work suggests that deep-learning based quantitative image analysis may be useful for distinguishing IDH-mutant GBMs on preoperative imaging.

CLINICAL RELEVANCE/APPLICATION

IDH-mutant GBMs are associated with increased survival and may benefit from maximal resection. Analysis of unique imaging features may help radiologists identify this tumor type on preoperative MRI.

PURPOSE

The two aims of this study are i) to measure DWI diagnostic reliability and compare it with that of CSF tests (i.e. RT-QuIC, 14-3-3 and tau); ii) to build a decision algorithm to diagnose sCJD subtypes using the MRI lesion profile obtained by DWI without and with codon 129 polymorphism (obtained with a blood test).

METHOD AND MATERIALS

A total of 1212 patients were recruited in this prospective study as part of a MRI consulting program. At autopsy the diagnosis of sporadic Creutzfeldt-Jakob disease (sCJD) was confirmed in 556 and ruled out in 150 patients. 506 patients were excluded because they are still alive or were lost to follow-up. A neuroradiologist blind to the diagnosis scored the DWI. A semi-quantitative method based on a four-point (0-3) ordinal scale was implemented to grade the hyperintensities of the DWI in 12 specific brain regions.To assess the inter-rater reliability (IRR) of the scoring system, other two neuroradiologists blind to final diagnosis scored DWI of 150 subjects. We measured the DWI diagnostic reliability in 706 patients, then we compared it with those of CSF tests in a subset of 399 patients (339 sCJD and 60 non prion) that had undergone MRI, 14-3-3 and tau tests. To predict the sCJD subtype with the MRI lesion profile, we built an algorithm in the form of a decision tree.

RESULTS

The overall diagnostic reliability of DWI in 706 patients was 0.94 sensitivity and 0.97 specificity. The IRR among the three neuroradiologists was excellent (above 0.80) in 10 over 12 brain regions. Furthermore, in the subset of 399 patients the sensitivity and specificity of DWI (0.94 and 0.97) surpassed those of 14-3-3 (0.84 and 0.34) and tau (0.87 and 0.63). The decision algorithm produced 9 distinct MRI phenotypes that characterized the five sCJD pure subtypes. Key steps in the algorithm are the presence of DWI hyperintensity in the neocortex, striatum, thalamus and cerebellum. The accuracy in predicting the correct subtype was about 0.62 and increased to 0.90 if the codon 129 polymorphism was considered.

CONCLUSION

Diagnostic reliability of MRI for the early diagnosis of sCJD is excellent. The study also provides the neurologists with a diagnostic algorithm for subtype identification at the patient's bedside.

CLINICAL RELEVANCE/APPLICATION

Diffusion MRI is an excellent test for diagnosis of sCJD. Subtype diagnosis with MRI may help to determine prognosis and direct therapies when they will become available.

SSG11-02 Comparative Analysis of Diffusion Kurtosis Imaging, Diffusion Tensor Imaging, and Diffusion

Weighted Imaging in Grading and Assessing Cellular Proliferation of Meningiomas

Tuesday, Nov. 27 10:40AM - 10:50AM Room: E351

Participants

84088100@qq.com

PURPOSE

To prospectively evaluate and compare diffusion kurtosis imaging (DKI), DTI and DWI metrics in determining the grade and cellular proliferation of meningiomas.

METHOD AND MATERIALS

Consecutive 96 patients with histopathologically confirmed meningiomas were included in this study. Mean kurtosis (MK), radial kurtosis (Kr), axial kurtosis (Ka), fractional anisotropy (FA), mean diffusivity (MD), and ADC were semi-automatically obtained in the solid components of tumors. Each normalized diffusion value was compared between high-grade meningiomas (HGMs) and low-grade meningiomas (LGMs) by using the Mann-Whitney U test. Receiver operating characteristic, multiple logistic regression, and Pearson correlation analysis were used for statistical evaluations.

RESULTS

DKI metrics (MK, Kr, and Ka) were significantly higher in HGMs than in LGMs ($P <= .001$). MD and ADC were significantly lower in HGMs than in LGMs ($P < .003$, and $= .002$). MK had significantly greater area under curve values than MD and FA in differentiating HGMs from LGMs ($P = .038$, and $.002$). MK was the only variable that could be used to independently differentiate HGMs and LGMs ($P < .001$). Significant correlations were found between Ki-67 labeling index and kurtosis metrics ($P < .001$), as well as for MD and ADC ($P = .004$, and $.007$).

CONCLUSION

In conclusion, diffusion techniques, including DKI, DTI and DWI, were useful in grading meningiomas. Moreover, MK demonstrated a better diagnostic efficiency than DTI metrics and was most closely associated with the grade of meningiomas. In addition, diffusion metrics showed great potentials in reflecting the cellular proliferation of meningiomas.

CLINICAL RELEVANCE/APPLICATION

Compared with other diffusion metrics, MK may serve as an optimal parameter for evaluating and predicting the grade of meningiomas. Moreover, diffusion metrics may potentially reflect the cellular proliferation.

SSG11-03 Event-Based Model of Diffusion MRI Shows that sCJD Strains Have Similar Epicenter but Different Lesion Propagation in the Brain

alberto_bizzi@fastwebnet.it

PURPOSE

Sporadic Creutzfeldt-Jakob (sCJD) is a very heterogeneous prion disease with five subtypes or strains that have different clinical presentation and survival times. We tested the hypothesis that different subtypes have different path of lesion propagation in the brain. This study aimed at modeling the DWI signal abnormalities spreading in 5 pure strains, in order to determine the epicenter (starting point) and the sequence of propagation of prion lesions in 12 brain regions.

METHOD AND MATERIALS

We considered a novel data-driven model, the event-based model (EBM), recently introduced to study the evolution of Alzheimer's and Huntington's diseases. The EBM describes the disease progression as a sequence of events, defined as the switching from a normal to an abnormal state for a biomarker of a patient. Considering a set of 12 events related to the appearance of DWI hyperintensity in 12 specific brain regions, the EBM finds the most likely sequence of DWI abnormalities given the observed DWI measurements of the subjects. A neuroradiologist blind to the pathological diagnosis visually scored the DWI of 306 patients with definite autopsy diagnosis of sCJD subtype and 123 patients with rule-out diagnosis of prion disease. An ordinal scale (0-3) was implemented to visually score the images and grade the DWI hyperintensities in 12 brain regions. Patients with 5 sCJD pure subtypes were included: MM/MV1 (n=89), MM/MV2C (n=42), MV2K (n=22), VV1 (n=15) and VV2 (n=49). The EBM sequences were based on cross-sectional data and their longitudinal consistency was validated comparing the stages at follow-ups with the baseline.

RESULTS

Results showed that the 5 sCJD strains have different sequence of lesion propagation. The anterior cingulate cortex was affected very early in all strains. Then, three propagation trajectories emerged from the orderings: neocortex is affected before striatum in MM/V1 and MM/V2C; striatum is affected before neocortex in VV2 and MV2K; limbic regions are affected before neocortex and striatum in VV1.

CONCLUSION

The EBM is a good model to determine DWI signal abnormality propagation in the brain. The 5 main sCJD strains share the epicenter but have a different path of lesion propagation in the brain.

CLINICAL RELEVANCE/APPLICATION

EBM provided for the first time data-driven models of spreading of DWI signal hyperintensities in sCJD subtypes. This result may have an impact on patient management and clinical trials.

SSG11-04 Q-Space Trajectory Imaging to Untangle the Source of Microstructural Abnormalities in Schizophrenia Subjects

Tuesday, Nov. 27 11:00AM - 11:10AM Room: E351

ofer@bwh.harvard.edu

PURPOSE

To untangle the microstructural sources of white matter abnormalities that are commonly identified in schizophrenia patients by using q-space trajectory imaging (QTI) that separates abnormalities into three microstructural domains: orientation coherence (Cc), size variance (CMD) and microscopic anisotropy (Cμ).

METHOD AND MATERIALS

QTI was measured with tensor-valued diffusion encoding (b-tensors), using non-conventional gradient waveforms, on a 3T MAGNETOM Prisma scanner (Siemens Healthcare GmbH). b-tensors were shaped as sticks, planes and spheres (b=0, 50, 250, 500, 1000, and 2000 s/mm2), totaling 95 volumes. Resolution was 2x2x4 mm3, 35 slices, TE=145ms, TR=6500ms, in 12:54 minutes. Participants were 21 inpatient subjects suffering from SZ (4F/17M; mean age 34.9), and 18 controls (4F/14M; mean age 32.6). All participants provided informed consent, and the study was approved by the local institutional review board. The QTI analysis yielded four measures: Cμ , Cc, CMD and macroscopic anisotropy (CM) which is proportional to Diffusion Tensor Imaging (DTI) Fractional Anisotropy (FA). Images were registered to MNI space and FA was used to extract the white matter skeleton, on which the four measures were projected, averaged and group compared using a general linear model with age and gender as covariates.

RESULTS

Significantly lower FA (p=0.038) in SZ subjects was explained by a significant decrease in microscopic anisotropy, Cμ. Differences in orientation coherence, Cc, were not significant (p=0.445), and an increase in size variance, CMD, did not reach significance threshold (p=0.115).

CONCLUSION

We disentangle DTI's FA differences into three domains, showing that the reduction of FA is best explained by a reduction of microscopic anisotropy in white matter rather than increased orientation dispersion, or size variability. Since microscopic anisotropy describes the shapes of microenvironments, regardless of orientation (e.g., dispersion), macroscopic arrangement (e.g., crossing fibers), and size variability (e.g., partial volume) our results suggest that in this population of SZ patients the microstructural shape of white matter is altered, which supports an interpretation of axonal degeneration or demyelination.

CLINICAL RELEVANCE/APPLICATION

Untangling microstructural abnormalities helps identifying underlying pathologies in brain disorders with potentially co-occurring pathologies such as schizophrenia.

SSG11-05 Diffusion Tensor Imaging of Human Optic Nerve Observes Gaze Evoked Changes

Tuesday, Nov. 27 11:10AM - 11:20AM Room: E351

Participants
Kenneth T. Wengler, MS, Stony Brook, NY (*Abstract Co-Author*) Nothing to Disclose
David Ouellette, MS, Stony Brook, NY (*Presenter*) Nothing to Disclose
Tao Wang, Stony Brook, NY (*Abstract Co-Author*) Nothing to Disclose

Tim Duong, PhD, Stony Brook, NY (*Abstract Co-Author*) Nothing to Disclose
Xiang He, PhD, Stony Brook, NY (*Abstract Co-Author*) Consultant, Endo International plc

PURPOSE

Several disorders affect the optic nerve (ON) that are potentially life- and sight threatening. Disorders such as papilledema and ischemic optic neuropathy result in changes to the peripapillary basement membrane caused by ON abnormalities; changes are

known to vary with eye position. DTI allows for non-invasive in vivo assessment of ON structural integrity, providing useful information in the manifestation, progression and recovery of several disorders. This information may detect pathological changes earlier than established methods such as optical coherence tomography (OCT).

METHOD AND MATERIALS

Eight healthy participants were recruited for this IRB approved study on a Siemens Prisma 3T magnet using a single channel loop coil placed over the left eye. A zoom-RESOLVE DTI acquisition was developed to image the ON. The total acquisition time was ~2 min for 20 diffusion directions with b = 800s/mm2. Each subject was imaged with visual fixation at three locations; primary position, ~20° abduction and ~20° adduction. Three repetitions were acquired at each gaze with ~30 sec rest between scans. Structural bSSFP images with 0.8mm3 isotropic resolution were acquired at each visual fixation for planning of each DTI acquisition. DTI data was processed using DSI studio to calculate RD, AD and FA maps. ON regions of interest were automatically calculated for each DTI acquisition using a previously developed method by Spees et al.

RESULTS

Compared to primary, abduction resulted in 15.5%, 10.6%, 12.9% and 0.7% increases in RD, AD, MD and FA respectively. Adduction compared to primary position resulted in 16.6%, 8.8%, 14.3% and 1.7% increases in RD, AD, MD and FA respectively. Compared to abduction, adduction resulted in 1.0%, -1.6%, 1.2% and 1.7% increases in RD, AD, MD and FA respectively.

CONCLUSION

A zoom-RESOLVE DTI method was used to investigate gaze evoked changes in ON DTI parameters. Previous MRI of the ON suggested that the ON sheath is the principal load bearing structure in adduction. This study suggests that some of this strain is also transferred to the ON itself. Gaze evoked changes in diffusion characteristics have the potential to assess diseases that affect the ON.

CLINICAL RELEVANCE/APPLICATION

Gaze evoked changes in diffusion characteristics have the potential to assess diseases that affect the optic nerve before the manifestation of ocular anatomical changes observed in OCT.

SSG11-06 Multi-Center Study Demonstrates Radiomic Texture Features Derived from MR Perfusion Images Predict Pseudoprogression from True Progression in Glioblastoma Patients

RColen@mdanderson.org

PURPOSE

To differentiate between pseudoprogression and true progression in patients with glioblastoma using MR perfusion radiomic texture analysis (TA)

METHOD AND MATERIALS

98 patients with pathologically-proven diagnosis of GBM were retrospectively included in this IRB approved HIPAA compliant study. All patients underwent DSC and DCE Perfusion MRI as part of their routine clinical care. Images were analyzed using Nordic ICE 2.3 (NordicNeuroLab) ; rCBV and ktrans maps were obtained. Subsequently, 3D slicer 4.3.1(http://www.slicer.org) was used to segment the entire tumor on the different processed maps to create a volume of interest (VOI) for Radiomic TA. Multiple invariant texture features where then extracted from each VOI. 310 invariant texture features were applied to each map. Radiomic texture features selection was performed using Maximum Relevance Minimum Redundancy (mRMR) feature selection method to narrow down the feature count to the top few hundred features. Two different supervised learning algorithms were evaluated in this analysis for classification and predictive model building, namely Support Vector Machine (SVM) and decision tree algorithm (C5.0). Cross validation was performed using the Leave One Out Cross Validation (LOOCV) approach for the SVM method, and k-fold cross validation (k=10) for the C5.0 method to see if the best model obtained had high accuracy, sensitivity and specificity to descriminate between pseudoprogression and true progression patients

RESULTS

We achieved an accuracy of 90.82% (AUC 89.10%, sensitivity 91.36%, specificity 88.24%, p-value 0.017), when using 60 out of 620 radiomic features obtained from both Ktrans and rCBV pharmacokinetic maps coupled with SVM,Variance and sum entropy were the two most significant radiomic features that discriminated between pseudoprogression and true progression.

CONCLUSION

Radiomic TA derived from perfusion images can be helpful in determining true versus pseudoprogression in GBM. Further, this study illustrates successful application of radiomic TA as an advanced processing step for different MRI perfusion maps (DCE, DSC)

CLINICAL RELEVANCE/APPLICATION

MR perfusion radiomics texture analysis (TA) as a potential noninvasive imaging surrogate to differentiate between True and pseudo progression in glioblastoma

SSG11-07 Reproducibility of Hadamard Encoded Multi-Delay 3D pCASL

Tuesday, Nov. 27 11:30AM - 11:40AM Room: E351

Participants
Alexander D. Cohen, PhD, Milwaukee, WI (*Presenter*) Nothing to Disclose
R. Marc Lebel, Calgary, AB (*Abstract Co-Author*) Employee, General Electric Company

For information about this presentation, contact:

acohen@mcw.edu

PURPOSE

Arterial spin labeling (ASL) can be confounded by varying arterial transit times (ATT) across the brain and with disease. In this study, a Hadamard encoding scheme was used to acquire multiple post-labeling delays (PLD), which were used to estimate ATT and corrected CBF. The goal of this study was to assess the reproducibility of this sequence in a set of normal volunteers to be able to apply it to clinical patients.

METHOD AND MATERIALS

Imaging was performed on 31 healthy male subjects at 4 time points (TPs) over 45 days. An 'enhanced' 3D pCASL (eASL) sequence was acquired with seven delays (1.0-3.3s) using Hadamard encoding. A long (4.0s) labeling block was divided into 7 sub-boluses with control and label sub-boluses corresponding to the Hadamard matrix. Images for each delay were extracted using a linear combination of the eight images. T1-weighted anatomical images were acquired for registration. Uncorrected flow (Flow) was obtained by averaging the delay images. ATT and corrected flow (cFlow) were also computed. Mean gray matter reproducibility was analyzed using the within and between subject coefficient of variation (wCV and bCV) and the repeatability coefficient (RC).

RESULTS

Mean cFlow was significantly higher than Flow (56.3±6.9 vs. 47.5±6.9 mL/100g/min, $p<10^{-6}$). Mean ATT was 1335±62 ms. wCV was significantly lower for cFlow compared to Flow (0.079±0.038 vs. 0.089±0.047, $p=0.005$) and for TD (0.029±0.015) compared to Flow and cFlow ($p<10^{-7}$). bCV followed a similar trend, but was higher compared to wCV (0.142±0.018, 0.121±0.011, 0.046±0.010 for Flow, cFlow, and TD respectively). The RC, normalized to the mean, was 0.300, 0.255, and 0.092 for Flow, cFlow, and ATT respectively.

CONCLUSION

wCV was less than 10% for the majority of subjects, and was lower than bCV indicating eASL is a robust tool for measuring changes in CBF and ATT over time. Corrected CBF was more reproducible compared to uncorrected CBF. ATT was very repeatable with wCV and bCV less than 5 percent.

CLINICAL RELEVANCE/APPLICATION

Corrected CBF and ATT can be measured with eASL in the same scan time as traditional ASL acquisitions. These metrics are stable across time allowing for changes over time to be reliably evaluated.

SSG11-08 Multi-Shell-Multi-tissue Gray Matter-Based Spatial Statistics: A Framework for Voxel-Wise Gray Matter Microstructure Analysis

PURPOSE

Indices derived from emerging multi-shell diffusion weighted-based modeling techniques (e.g., NODDI) can be used to assess gray matter (GM) microstructure. Accurate tissue segmentation and between-subject registration are critical steps for optimal voxel-wise/vertex-wise analysis of these indices to localize changes related to brain development and disease. Most current methods rely on tissue segmentation of structural images followed by fine registration between diffusion-weighted and structural images, which suffer from poor between-modality registration. In this study, we used multi-shell multi-tissue constrained spherical deconvolution (MSMT-CSD, for accurate single-step tissue segmentation of diffusion images) followed by GM-based spatial statistics (GBSS, for between subject registration) and present example results from voxel-wise heritability analysis on Human Connectome Project (HCP) data.

METHOD AND MATERIALS

After quality control, data from 600 healthy adult participants in HCP (S900 release) with [illegible] multi-shell diffusi

After quality control, data from 689 healthy adult participants in HCP (S900-release) with the complete set of multi-shell diffusion-weighted MRI were used. Orientation dispersion (ODI) and neurite density indices (NDI) were generated using the NODDI toolbox for all brain voxels. Diffusion-weighted images were segmented using MSMT-CSD (MRtrix). GBSS was performed to generate skeletonized maps of GM neuritic indices. Voxel-wise heritability analyses were performed using the Fast and Powerful Heritability Inference (FPHI) toolbox with threshold-free clustering. To further scrutinize GM regions with highly significant heritability, hard-threshold-based clustering was performed at uncorrected-P<0.01.

RESULTS

GM-ODI showed high heritability across the cortex, hippocampi, and amygdalae (FWE-P<0.0001), with both amygdalae surviving secondary more conservative clustering. In contrast, no significant GM-NDI heritability was observed.

CONCLUSION

We demonstrated successful implementation of a new framework for voxel-wise analysis of gray matter microstructure. Across the "healthy GM" spectrum, GM-ODI is significantly affected by genetic factors. Our results suggest that GM-ODI can serve as a candidate in studies of neural endophenotypes underlying the heritable pathology of brain disorders and GM-NDI may be considered as an environmentally-modifiable treatment target for neuropsychiatric traits.

CLINICAL RELEVANCE/APPLICATION

MSMT-GBSS can improve localization of gray matter microstructural variations in health and disease.

SSG11-09 Intrinsic Diffusivity Encoding of Arterial Labeled Spins (IDEALS) for Whole Brain Water Permeability Mapping with MRI

Tuesday, Nov. 27 11:50AM - 12:00PM Room: E351

PURPOSE

Blood-brain barrier (BBB) disruption has been linked to multiple neurological diseases and psychiatric disorders. Water molecules are several times smaller than most exogenous contrast agents and transcapillary water exchange is mainly facilitated by active, transcellular transport mechanisms. As such, BBB water permeability, extraction fraction (Ew) and permeability-surface area product (PSw), could provide a more sensitive assessment of BBB dysfunction. Here we propose a novel MRI-based approach, Intrinsic Diffusivity Encoding of Arterial Labeled Spins (IDEALS), to non-invasively map whole-brain BBB water permeability.

METHOD AND MATERIALS

In IDEALS, intra and extravascular labeled water after pCASL preparation are separated by the intrinsic diffusion sensitivity of the segmented 3D-GRASE acquisition that manifests as a point spread function (PSF) in the image domain. The PSFs differ for intra and extravascular labeled spins and are highly dependent on the segmentation scheme. The PSFs were estimated using augmented extended phase graphs and the extravascular signal fraction was estimated by deconvolution. Two post-labeling delay (PLD) values were adopted. A PLD of 2sec was used to estimate cerebral blood flow (CBF), Ew after T1 correction of the extravascular signal fraction, and PSw according to the Renkin-Crone equation. A PLD of 1sec was used to calculate the arterial transit time (ATT). Ten healthy participants were recruited for this IRB approved study. All studies were performed on a Siemens 3T MRI. Total acquisition time was 15min for 4 sets of ASL images; 2 PLDs and 2 segmentation schemes.

RESULTS

Gray matter averages were 1.39sec, 55.7mL/100g/min, 85.8%, and 112.9mL/100g/min for ATT, CBF, Ew, and PSw respectively. White matter averages were 1.47sec, 41.3mL/100g/min, 87.4%, and 84.5mL/100g/min for ATT, CBF, Ew, and PSw respectively. Both Ew and PSw values are in good agreement with PET-based measurements.

CONCLUSION

Encouraging initial results using IDEALS was reported in this study. This novel approach provides whole-brain BBB water permeability maps at comparatively high spatial and temporal resolutions without a MRI contrast agent.

CLINICAL RELEVANCE/APPLICATION

BBB breakdown has been hypothesized as a key mechanism in neurological and psychiatric diseases. The proposed noninvasive method, IDEALS, allows for repeated measurement of BBB integrity without the potential side effects of gadolinium-based contrast agents.

CONCLUSION

The CBCT scan may result in higher radiation dose, even exceeding the dose from conventional MDCT scan. Using lower x-ray tube current allowed 3.8-fold dose reduction without clinically significant degradation of image quality. The DLP method provided good estimate of patient effective dose.

Background

Hybrid imaging modalities provide anatomic and functional information improving diagnostic accuracy but also increase patient radiation dose. Combining a cone beam CT (CBCT) with SPECT may result in high radiation exposure due to lack of tube current modulation. The purpose of our investigation was to assess radiation dose for clinical CBCT protocols as part of SPECT/CT examinations and to evaluate dose reduction options.

Discussion

Effective doses calculated from the measurements were 4.21 mSv and 1.11 mSv for 20 mA and 5 mA respectively. The DLP method resulted in very similar values with the differences of 0.05% at 20 mA and 4.76% at 5 mA. With lower tube current image noise was increased by 35%. That was found acceptable for localization and attenuation correction of SPECT data.

SSG12-02 Strategy and Results for Characterization of Dose Outliers in CT Dose Monitoring: Analysis Across 84683 Patient Studies

PURPOSE

The Joint Commission mandates monitoring of individual patient doses from CT and investigation of outliers. The mechanics of this process was left for the institution to determine. This study presents a novel strategy to identify and characterize dose outliers in a large academic medical center.

METHOD AND MATERIALS

With IRB approval, for the calendar year of 2016, 84,683 CT exams were recorded in an in-house dose monitoring program. For each protocol using AEC, radiation dose and patient diameter was fitted to an exponential relationship. The dose value from the fitting for a patient was considered to be ideal for the given diameter. A patient with higher than 99%ile dose for his/her diameter was flagged as a dose outlier. To streamline the severity of over-dosing and thus prioritizing the investigation of outliers, a dose

deviation index (DDI) was calculated for each outlier as the ratio of received dose and ideal dose minus one. All outliers were investigated by two senior CT technologists by carefully examining the techniques and images. The CT physicist then categorized the found reasons and tagged each outlier with all reasons applicable to that case.

RESULTS

Over 50% of the dose outliers had a DDI between 1-2. A total of 18 different reason categories were identified. Out of the 661 dose outliers, about half were due to multiple accession number grouped together due to dose values extracted from screenshot of the dose reports, a problem resolved when radiation dose structure report can be used in the dose monitoring report. Another common reason for high dose (25%) was correlated with use of high kV, rotation time, or both with extra-large patients. Wrong positioning including patients unable to raise their arms (13%) was the third common issue.

CONCLUSION

A strategy was devised to survey patient CT dose and characterize the dose outliers. The identified categories are representative reasons of high radiation dose in CT imaging, and can be used as reference reasons for the community. The tagged data set can further be used as a training set for machine learning algorithm to automatically characterize the outliers in the future.

CLINICAL RELEVANCE/APPLICATION

A strategy was devised to survey large scale patient CT dose, identifying dose outliers, and characterize the outliers. The identified categories are representative reasons of high radiation dose in CT imaging, and can be used as reference reasons for the community.

SSG12-03 A Data-Centric Strategy for Developing CT Dose and Noise Reference Levels from Clinical Patient Populations

PURPOSE

To develop a data-centric strategy solution for developing CT dose and noise reference levels across large clinical patient populations and in CT scanners.

METHOD AND MATERIALS

This IRB-exempt study evaluated CT abdominopelvic (AP)-related examinations performed in 2017 by 22 scanners from two vendors with 11 models in 3 site hospitals. An in-house developed informatics system automatically extracted protocol information, patient size (cross-sectional diameter), dose, and in vivo noise magnitude within images. Protocol nomenclature categorization was performed using a decision tree machine learning algorithm. Four reference patient size intervals were identified: 13-20, 20-30, 30-40, and 40-50 cm. Noise Reference Level (NRL), Noise Reference Range (NRR), Dose Reference Level (DoRL), and Dose Reference Range (DoRR) were defined for each size range as the median and interquartile interval of noise and dose, respectively.

RESULTS

60,000 CT AP studies with 64 different convolution kernels for patients ages 0-70 and sizes 13-48 cm were identified. NRLs ranged between 15.8 to 18.4 HU with NRRs for the four size ranges were the following: 13.2-24.7,12.6-22.5,12.5-23.2, and 12.1-22.8 HU. DoRLs ranged within 11.9-16.1 mGy. The four DoRRs were 9.5-21.4,7.9-17.3,9.9-21.3, and 10.8-23.2mGy.

CONCLUSION

This study offers the first even data-crunching solution for developing CT dose and noise reference levels using clinical patient data. New reference levels and ranges simultaneously consider image noise and radiation dose information across patient populations. The new metrics enables prospective optimization of clinical practice to maximize the imaging benefit and patient safety.

CLINICAL RELEVANCE/APPLICATION

A new solution is introduced for simultaneously defining image quality and dose reference levels across different patient body habitus. The methodology enables prospective optimization of clinical practice to maximize the imaging benefit and patient safety.

SSG12-04 Does the Dose Reduction Associated with a Percentage Increase of a CT Statistical Iterative Algorithm Maintain the Detectability of Low-Contrast Details? A Phantom Study

PURPOSE

To verify if the dose reduction combined with increasing percentages of the ASIR-V algorithm was associated with a maintenance of detectability of low contrast details in the abdominal area.

METHOD AND MATERIALS

An anthropomorphic chest and abdomen phantom containing a liver equivalent insert with details of 10 HU relative contrast was repeatedly scanned with a GE Revolution CT equipment. Given a fixed level of noise index (18 HU combined with a thickness of 1.25 mm), the images were acquired without iterative algorithm and with percentages of ASIR-V of 30%, 50% and 70%. The correspondent dose reductions determined by the tube current modulation system were 48%, 67% and 83%, respectively. The same images were then reconstructed using only FBP, at an ASIR-V percentage of 0%. Five radiologists evaluated randomized image data sets with and without details, scoring the lesion presence on a five-point diagnostic confidence scale and the area under the roc curve (AUC) was calculated as figure of merit. The human observer results were then compared with AUC obtained with a Channelized Hoteling Observer (CHO). CNR values were also measured.

RESULTS

For human observer, AUC values were in the range 0.90-0.93 for images acquired without ASIR-V and with percentages of 30% and 50%, whereas with ASIR-V at 70% the AUC decreased significantly to 0.81. Diagnostic accuracy for FBP reconstructed images were always inferior to ASIR-V images, with an AUC decrease between 6 and 9%. The behaviour of the CHO was coherent with human observer results, with lower AUC differences between FBP and ASIR-V images (from 2 to 6 %). CNR values were stable for the different ASIR-V percentages, confirming the right functionality of the current modulation system, whereas progressively decrease with dose for FBP reconstructed images.

CONCLUSION

The iterative ASIR-V algorithm maintained low contrast detectability and the diagnostic accuracy up to a dose reduction of 67%, consequent to the application of a 50% level with automatic tube current modulation. At further dose reductions with greater iterative percentages, a significant decrease of detectability and diagnostic accuracy was observed.

CLINICAL RELEVANCE/APPLICATION

Prior to define the iterative level combined with dose reduction in a clinical protocol, the maintenance of low contrast detectability must be verified with ROC studies done with human or model observers.

SSG12-05 Effective Dose for Computed Tomography in Large, Clinical Populations

PURPOSE

Effective dose can efficiently integrate multiple organ dose values into a singular scalar value of radiation dose. The effective dose can also be calculated using dose length product (DLP) to effective dose conversion coefficients. The purpose of this study was to compare the results from these two methods across a large clinical population.

METHOD AND MATERIALS

This IRB-approved study included 579 chest and 247 abdominopelvic exams from two scanners. The organ doses were estimated based on an established Monte Carlo method. Each patient was matched to an XCAT anthropomorphic phantom of the same anatomical height. Precomputed Monte Carlo data were then applied along with adjustments for tube current modulation and patient size. A bias correction factor was also applied to each organ dose to calibrate the organ doses to validated ground truth dose values. The effective dose of each exam was calculated using both dose-length-product based (EDk) and organ-dose-based (EDOD) methods. The EDk was estimated by extracting the DLP and DLP-to-effective dose conversion coefficients defined by ICRP 102. The EDOD was derived using the patient-informed organ doses from the exam using ICRP 103 weighting factors. The EDk was compared to EDOD and CTDIvol.

RESULTS

For the abdominopelvic protocol, EDk was > EDOD by 80.2±48.7% on average (min: -28%; max: 235%; median: 75%). For the chest protocol, EDk was > EDOD by 64.1±33.1% on average (min: -18%; max: 191%; median: 60%). EDk was highly influenced by mean CTDIvol (abdominopelvic: R=0.9692, chest: R=0.9557). EDk was higher than EDOD, especially for larger patients (abdominopelvic: 9.6%, 66.2%, and 115.6% higher; chest: 30.2%, 77.9%, and 116.2% higher on average for patients with 22, 30, and 35 cm water equivalent diameters, respectively). This can be attributed to the contribution of doses absorbed by remainder tissue in EDk calculations.

CONCLUSION

In this work, we compared the effective dose calculated using DLP-based methods versus those based on organ dose. The result showed that DLP methods may over-estimate effective dose, especially for larger patients

CLINICAL RELEVANCE/APPLICATION

This clinical cohort study showed the substantial differences of effective dose estimated using DLP vs. organ-dose-based methods. This effect is more prominent for larger patients. The study indicates that radiation dose monitoring and reporting could benefit from accurate and robust organ dose estimation.

SSG12-06 Addressing Limitations of the ACR DIR Patient Size Measurement Method

Tuesday, Nov. 27 11:20AM - 11:30AM Room: S404CD

PURPOSE

AAPM Reports 204/220 reported the relationship between patient size surrogates and normalized dose coefficients (NDC) needed for size-specific dose estimates (SSDE). When localizer radiographs are used to calculate SSDE then a magnification correction should be applied. In this study, we demonstrate a new patient-model based magnification correction on patient data. We also discuss limitations to thresholding based size measurements for bariatric and pediatric patients.

METHOD AND MATERIALS

We analyzed 573 patient scans obtained from a clinical CT system under IRB approval. There were 229 adult abdomen, 284 adult chest, 48 pediatric abdomen, and 12 pediatric chest exams. We extracted LAT and AP dimensions from CT localizers using the ACR DIR method and a connected component analysis to extract gold standard LAT and AP dimensions from axial CT images. We extracted table height from the DICOM header. We applied the model-based magnification correction to the AP and LAT dimensions from the localizers. We used the equation from AAPM Report 204 to calculate the NDC. 'Gold' standard NDC values were derived using effective diameter measurements from axial CT images. We plot the NDC for our model-based correction and ACR DIR method as a function of the gold standard NDC values.

RESULTS

NDC estimates for the model-based approach have excellent correlation (R2 = 0.92) with the gold standard approach. On average, effective diameter for the ACR DIR and model-based methods are 8.0% and 1.0% greater than the gold standard, respectively. Outlier cases were noted caused by patient truncation, arms down or devices on patients. ACR DIR size extraction method failed for small patients due to the CT couch being included in the size measurement and bariatric patients were underestimated as some of their anatomy was classified as belonging to the CT couch and thresholded away.

CONCLUSION

The model-based magnification method gives an accurate estimate of effective diameter needed for calculating NDC to achieve accurate SSDE. We discuss errors associated with threshold based size methods for very small and very large patients.

CLINICAL RELEVANCE/APPLICATION

We demonstrate how thresholding based size methods, like those used by the ACR DIR fail for very small and very large patients.

SSG12-07 Characterization of Radiation Risk across a Clinical CT Patient Population: Comparison across 12 Risks Metrics

francesco.ria@duke.edu

PURPOSE

Ascertaining radiological procedure radiation burden is essential for justification, optimization, and personalization of the procedure. While the exact radiation risk for an individual exam is unknowable, various risk-related figures have been used as surrogates, e.g., device output metrics such as CTDI, DLP, SSDE, and hypothetical constructs such as Effective Dose (ED) and Risk Index (RI) that take into account specific organ risks, age, and gender factors. Purpose of this study was to compare how twelve different radiation risk metrics characterize the radiation burden across a set of clinical CT examinations differently.

METHOD AND MATERIALS

This IRB-approved study included 265 abdominopelvic exams with contrast. Organ doses were estimated using Monte Carlo methods. The following risk metrics were calculated using previously validated methods: CTDIvol, DLP, SSDE, DLP-based ED (EDk), organ-dose-based ED (EDOD), dose to a defining organ (ODD to stomach), organ-dose-based RI (RI), and RI for a reference 20 y.o. patient (RIr). Additional metrics of ODD,0, ED0, and RI0 were calculated for a reference patient (ICRP 110). Lastly, inspired by the ICRP, an adjusted ED (ED') was computed as the product of RI/RIr and EDOD. A linear regression was applied to each metric dependency to the patient water equivalent diameter (WED). Fit slopes (FS) and relative interquartile ranges (rIQR) at 30 cm reference WED were calculated and normalized to those of RI, which was assumed to be the actual patient risk closest surrogate.

RESULTS

Results showed significant differences between the metrics. EDOD exhibited closest concordance with RI, followed by ODD. Normalized FS ranged between 0.99 (ED') to 2.24 (DLP), and normalized rIQR ranged between 0.30 (DLP) to 4.03 (ED').

CONCLUSION

Different risk metrics lead to different characterization of population risk, particularly risk overestimation for large patients and underestimation for small patients. Furthermore, the risk variability across a population is underestimated for most variables except ED', which exhibits more variability and radiation risk individualization. Care should be exercised in drawing risk predictions from unrepresentative risk metrics applied to a population.

CLINICAL RELEVANCE/APPLICATION

Different risk metrics can lead to different risk predictions. There is a need to standardize risk metrology for proper justification and optimization of radiological procedures.

SSG12-08 Effect of Simulated Micro-Dose (mD) CT on the Performance of Neural Network Convolution (NNC) Deep-Learning (DL) In Radiation Dose Reduction in Chest CT

PURPOSE

Radiation dose reduction in chest CT is highly demanded since current radiation dose is high for lung cancer screening. Our purpose was to investigate the effect of simulated mDCT images on the training and performance of our 3D NNC DL for radiation dose reduction in chest CT.

METHOD AND MATERIALS

We developed anatomy-specific (AS) NNC models employing volume-based neural network regression in a convolutional manner to convert mDCT to higher-dose (HD)-like CT. We trained 3 AS NNC models with soft-gating layers with 3 anatomic areas under two training protocols. In our first protocol, we trained our NNC with an anthropomorphic chest phantom (Kyoto Kagaku, Kyoto, Japan) by utilizing real mDCT (120kVp, 10mAs, 0.37mSv) images as input and HDCT (120kVp, 550mAs, 34.9mSv) as "teaching" images. In a second protocol, we trained our NNC with simulated mDCT and HDCT from our diagnostic CT database of 20 patients. Our mDCT simulation consisted of forward-projection of HDCT, addition of photon and electric noise to the sinogram image, filtered back-projection of the noise component, and addition of the noise image to the original HDCT. Through training, our NNC learned to convert lower-dose CT to HD-like CT, where noise and artifacts are substantially reduced; thus, term "virtual" HD (VHD) CT. To compare our NNC models under two different protocols, we collected mD (120 kVp, 5 mAs, 0.2 mSv) and full-dose (120 kVp, 50 mAs, 2.0 mSv) CT of 50 clinical cases including 30 cases with nodules.

RESULTS

Our VHD technology converted mDCT to "virtual" HDCT where noise and artifacts were reduced substantially, while anatomic structures and pathologies were preserved. Our NNCs trained with real mDCT and simulated mDCT improved the contrast-to-noise-ratio (CNR) of mDCT of clinical cases from 4.1±3.9 dB to 21.5±4.9 dB and 22.7±5.0 dB, respectively, which were higher than that of "gold-standard" full-dose CT (CNR: 13.4±5.1 dB). Difference between the 2 models was not statistically significant (t-test; P=0.1).

CONCLUSION

Our 2 NNC models, using real and simulated mDCT images for training, achieved a similar dose reduction performance of 90% and converted mDCT of 50 clinical cases to VHDCT that have higher image quality than "gold-standard" full-dose CT.

CLINICAL RELEVANCE/APPLICATION

Substantial reduction of radiation dose in CT by our new VHD technology would potentially make mDCT screening possible, and it would be beneficial to screening population.

SSG12-09 Radiation Doses from the Dual-Layer Spectral Detector CT at Different Patient Sizes: Comparison with a Conventional CT Scanner

Tuesday, Nov. 27 11:50AM - 12:00PM Room: S404CD

Participants
Xinhui Duan, PhD, Dallas, TX (*Presenter*) Nothing to Disclose
Jeffrey B. Guild, PhD, Dallas, TX (*Abstract Co-Author*) Nothing to Disclose

Prabhakar Rajiah, MD, FRCR, Dallas, TX (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To compare the radiation doses from the dual-layer spectral detector CT (SDCT) and a conventional CT scanner at different patient sizes.

METHOD AND MATERIALS

In this retrospective IRB-approved study, consecutive patients scanned on the SDCT scanner (IQon, Philips, Cleveland, USA) with chest CT (PE protocol) and abdominal CT (routine single portal venous phase) protocols from were included. A comparison group of patients scanned using the same matched protocols in a conventional 256- slice scanner (Brilliance iCT, Philips, Cleveland, USA) was selected. The radiation doses (CTDIvol) and the size (WED- Water equivalent diameter) was extracted using Radimetrics software (Bayer, Whippany NJ, USA). The radiation doses of the two scanners for these two protocols were compared by log transformation of the CTDIvol and using linear regression model to measure the differences in log (CTDI) on average when interacting with WED. The percentage difference between iQon and iCT was also calculated. Each variable was estimated using Maximum likelihood method and tested against the hypothesis of being zero (no effect). P value of less than 0.05 was considered as statistically significant. SAS 9.4(SAS Institute Inc., Cary, NC) was used for all analysis.

RESULTS

The study included 482 abdominal CTs (mean patient size 306.4 ± 38.3 mm (182.4 - 442.2 mm)) and 215 chest CTs (296.3 ± 34.1 mm (207.4 - 388.4 mm)) performed in IQon and 741 abdominal CTs (303.1 ± 44 mm (156.8 - 450.1 mm)) and 323 chest CT (299.6 ± 42.3 mm (205.5 - 408.2 mm)) in iCT. For the abdominal CTs, the mean CTDI for IQon was 12.0 ± 6.0(3.1 - 50.8) and for iCT was 11.7 ± 6.7 (2.8 - 44.5). For the chest CTs, the mean CTDI for IQon was 11.7 ± 6.2 (4.0-43.1) and for iCT was 6.3 ± 3.0 (3.9-57.0). The intercept was lower for iQon than that for the conventional CT ($p<.0001$). However, iQon has a higher slope ($p<.0001$). As a result, the percent difference in CTDvol between iQon and the conventional CT increased when the patient size increased.

CONCLUSION

With matched abdominal and chest CT protocols, the SDCT had lower CTDIvol than the conventional CT at small patient sizes, but slightly higher radiation dose than conventional CT at large patient sizes.

CLINICAL RELEVANCE/APPLICATION

Understanding the size-based variability of radiation dose from the SDCT will help in optimizing the dose and utilize the technique appropriately.

PURPOSE

To ensure generalization performance in various hospitals, we developed a deep learning based automatic Chest PA screening System which can detect 5 class findings and performs well on various devices. Its performance was evaluated by using FROC and FOM in various devices.

METHOD AND MATERIALS

Our system can detect 5 class findings which are nodule, consolidation, pleural effusion, interstitial opacity, pneumothorax. We used chest radiographs(PA view) collected from 2013 to 2015 at two hospitals. There were 18,869 labeled CRs comprised of 11,181 normal and 1,943 nodule, 1,293 consolidation, 1,867 pleural effusion, 1,406 interstitial opacity, 1,179 pneumothorax CRs. All abnormal CRs were clinically confirmed by CT scans. Thus, we could collected elaborate segmentation label data. Furthermore, our data were acquired in various devices, the first hospital has x-ray detectors from 3 manufacturers(GE, FUJI, Canon), and the other has devices from 2 manufacturers(Philips, LISTEM). We used only data from the first hospital for training and then used all data of other hospital as test data.

RESULTS

In the test dataset, our screening performance showed AUC of 0.99, with an sensitivity, specificity of 97.6%, 97.9%, respectively. For each class findings, Our system achieved FROC and FP per scan of 81.2% / 0.72, 84.4% / 1.41, 83.1% / 0.35, 85.7% / 1.45, 91.6% / 0.78 for nodule, consolidation, pleural effusion, interstitial opacity, pneumothorax, respectively. In FOM performance, sensitivity is 84.7%, 91.5%, 93.7%, 97.9%, 97.2%.

CONCLUSION

Our screening system demonstrated reliable performance in various devices and multi hospitals. It also showed competitive results in detecting location and classification of 5 class findings.

CLINICAL RELEVANCE/APPLICATION

Our system demonstrates reliable performance on various devices on multiple findings using CAD.

SSG13-02 Curriculum Learning from Patch to Image for Pulmonary Abnormal Pattern Screening in Chest-PA X-Ray: Intra- and Extra-Validation on Multi-Center Datasets

PURPOSE

To propose and validate a computer aided detection (CAD) for detecting 5 kinds of pulmonary abnormalities in chest-PA X-ray using multicenter data with a curriculum learning strategy to train entire images after training lesion-specified image patches to guide the CAD toward better local minima.

METHOD AND MATERIALS

Chest-PA X-rays collected from two hospitals, which consisted of 10137 healthy subjects and 3244 patients including 944, 550, 280, 1364, and 331 patients with nodule (ND), consolidation (CS), interstitial opacity (IO), pleural effusion (PE) and pneumothorax (PT) from XXX (X1), and 1035 healthy subjects and 4404 patients including 1189, 853, 1009, 998 and 944 patients with ND, CS, IO, PE and PT from YYY (Y1), respectively. 60% and 20% of X1 dataset were used for training and validation. 20% of X1 and Y1 datasets were used for test. Every abnormality lesion was manually drawn by expert thoracic radiologists. Using these regions, image patches were used to specifically train the regional patterns of abnormalities. Entire images were used to fine-tune the network subsequently. Modified resnet-50 architecture for multi-label problem was used to train weak supervisions. To assess the effectiveness of our approach, we compared it with or without this strategy using six-measures including area under the curve (AUC), accuracy, sensitivity, specificity, positive predictive value (PPV), and negative predictive value.

RESULTS

Both models converged well and weights were extracted at the minimum loss on validation set. With curriculum learning, the AUC in X1 test set was 93.2, 88.6, 97.7, 99.5, 96.6% for ND, CS, IO, PE, and PT, respectively. Compared to the model without this strategy, performance improvement was achieved in all metrics, and PPV showed the largest improvement of 11.3% and 4.6% for X1 and Y1.

CONCLUSION

The proposed curriculum learning strategy successfully showed the outperforming results compared with baseline through multicenter validation, which could be used in case of the smaller dataset with complex task.

CLINICAL RELEVANCE/APPLICATION

This curriculum learning strategy could be useful in case of computer-aided detection (CAD) on the smaller dataset with complex task such as CAD on abnormalities of chest-PA X-ray.

SSG13-03 Data Augmentation via Synthetic Mammograms for Improved Training of a Deep Learning Breast Mass Detection Algorithm

PURPOSE

To evaluate whether training data augmentation using synthetic mammograms may improve the performance of a deep learning system for mass detection.

METHOD AND MATERIALS

Synthetic mammograms were generated from procedurally generated compressed breast phantoms containing masses. The anthropomorphic phantoms were modeled for four different breast density categories, and the masses were modeled with different sizes, shapes and margins. MC-GPU, a Monte Carlo-based x-ray transport simulation code that generates clinically-realistic radiographic projection images, was used to project the 3D phantoms into synthetic mammograms. A total of 530 mammograms with 677 masses were generated. We used Faster R-CNN for our deep learning network with pre-training from ImageNet using ResNet-101 architecture. From the Curated Breast Imaging Subset of Digital Database for Screening Mammography (CBIS-DDSM) data set, we used 573 mammograms (607 masses) for training, and 170 mammograms (177 masses) for testing, all of which contained masses. We compared the detection performance of the Faster R-CNN when the network was trained using only the CBIS-DDSM training images, and when the network was augmented with the 530 synthetic mammograms. FROC analysis was performed to compare performances with and without the synthetic mammograms.

RESULTS

When trained on the CBIS-DDSM data set alone, the Faster R-CNN detected 68.4% (121/177) of the masses on the test set. With the augmented training set, the test set detection prescreening sensitivity was 83.6% (148/177). The difference between the two FROC curves was statistically significant using JAFROC ($p = 0.005$). At 1 false positive per image (FP/image), the test set detection sensitivity was 60.5% (107/177) when trained on CBIS-DDSM alone, and was 68.9% (122/177) when trained with the augmented data set. The difference was statistically significant using McNemar's test ($p = 0.001$).

CONCLUSION

Our study demonstrates that it is possible to generate high quality synthetic mammograms using procedurally generated breast

Our study demonstrates that it is possible to generate high quality synthetic mammograms using procedurally generated breast phantoms and Monte Carlo simulation, that can be used to enlarge the training data set and improve the performance of deep learning systems for mass detection on mammograms.

CLINICAL RELEVANCE/APPLICATION

Training data set can be a limiting factor for deep learning applied to medical imaging tasks. This study shows our synthetic mammograms are useful for data augmentation in computer-aided detection.

SSG13-04 Comparison of Transfer Learning and Deep Feature Extraction Strategies for Breast Cancer Classification in Mammography Using Deep Neural Networks

Tuesday, Nov. 27 11:00AM - 11:10AM Room: S404AB

Participants
Ravi K. Samala, PhD, Ann Arbor, MI (*Presenter*) Nothing to Disclose
Heang-Ping Chan, PhD, Ann Arbor, MI (*Abstract Co-Author*) Institutional research collaboration, General Electric Company
Lubomir M. Hadjiiski, PhD, Ann Arbor, MI (*Abstract Co-Author*) Nothing to Disclose

Nicholas Szerman, Ann Arbor, MI (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

To study the differences between using a pre-trained deep convolutional neural network (DCNN) as feature extractor and a fine-tuned DCNN using transfer learning for classification of malignant and benign masses in mammography.

METHOD AND MATERIALS

3,578 mass lesions from 3,411 mammograms were collected with IRB approval. Three DCNN structures: AlexNet, InceptionV1 (GoogLeNet) and VGG16 that had success in ImageNet classification were used in this study. All the DCNNs were pretrained on ImageNet data for a 1000-class object classification task and then applied to mammographic mass classification. When used as a feature extractor, the features from the first fully connected layers (*FF*) were extracted and a random forest classifier (RF-*FF*) is trained. Under the transfer learning paradigm, two transfer strategies: freezing up to the first convolutional layer (*CF*) and freezing up to the last convolutional layer (*CL*) were studied, which led to four mammography-trained classifiers: mDCNN-*CF* and mDCNN-*CL* with DCNN classifier (consisting of fully connected layers and softmax) and random forest classifier using *FF* features. All the strategies were validated in a 4-fold cross-validation approach while keeping all the views from the same patient together in the same fold. The experiments were repeated ten times with different random stochastic initializations.

RESULTS

ImageNet-trained feature extractor RF-*FF* obtained mean AUCs of 0.77, 0.58 and 0.74 for AlexNet, InceptionV1 and VGG16, respectively. Mammography fine-tuned mDCNN-*CF* and mDCNN-*CL* reached mean AUCs of 0.83 and 0.79, respectively, as the best among the three structures. mDCNN-*CF*-RF-*FF* and mDCNN-*CL*-RF-*FF* also reached similar AUCs of 0.83 and 0.79, respectively. The fine-tuned mDCNNs achieved higher accuracy than without transfer learning.

CONCLUSION

Although DCNN trained with images from a different domain may be used as a deep feature extractor for medical imaging, transfer learning in the target domain has significant advantages where some of the deeper layers can be fine-tuned for the target task. In transfer learning, replacing the DCNN classifier with an external classifier like the random forest classifier does not improve the classifier performance.

CLINICAL RELEVANCE/APPLICATION

With the prolific usage of deep learning in medical imaging, it is important to understand the effectiveness of the features extracted by different DCNN structures with and without transfer learning.

SSG13-05 Detecting Mal-Positioned Endotracheal (ET) Tubes in Portable Chest X-Ray (CXR) Images: Comparing Deep Learning Models with Hand-Engineered Approach on Carina Detection

Tuesday, Nov. 27 11:10AM - 11:20AM Room: S404AB

zhiminhuo@yahoo.com

PURPOSE

Comparing performances in detecting carina location from deep learning and hand-engineered approaches

METHOD AND MATERIALS

ET tubes are the most commonly used tubes for ICU patents. Mal-positioned ET tubes may lead to collapsed lungs. The ET tube tip placement relative to carina location in a CXR image is used to determine if an ET tube is properly positioned. However, the carina, a ridge of cartilage in the trachea that occurs between the division of the two main bronchi, can be hard to detect on CXR images. Our previously developed hand-engineered approach includes the detection of lungs, spine and aortic arch to identify an initial ROI. Carina location is detected using template matching and feature analysis within the ROI. In this study, we investigate convolutional neural networks (CNN) based models, i.e., the faster R-CNN and U-Net, to detect carina locations. The R-CNN was trained with initial weights from a pre-trained model. U-Net was trained from scratch. Both models were trained on 994 portable CXR images, validated on 136 images, and tested on 212 images. The carina location (x,y) on each image was identified by an experienced radiologist for the 212 testing images and by a trained scientist for the rest of images. The carina detection accuracy was measured by the distance between the human-identified and computer detected locations in terms of <=5mm, 10 mm and beyond.

Each image has only one detection from each approach; detections beyond 10 mm from the truth are regarded as a miss or FP detection.

RESULTS

R-CNN yielded sensitivities of 92% (98%) and 60% (88%) and 58% (87%) for <=5 (10) mm on the training, validation and testing data, respectively . U-Net yielded sensitivities of 94% (94%), 64% (85%) and 67% (89%) for <=5 (10) mm on the training, validation and testing data, respectively. Our hand-engineered approach yielded a sensitivity of 52% (74%) for <=5 (10) mm on the same 212 testing images. The CNN based models yielded a similar performance in detecting carina location measured within 10 mm of truth with more than 10% improvement on average than that of the hand-engineered approach.

CONCLUSION

Use of CNN based models substantially improved carina detection accuracy and performance robustness.

CLINICAL RELEVANCE/APPLICATION

Accurate detection of carina locations in CXR images can help timely detection of mal-positioned ET tubes, thus improving the care and treatment management for critically ill patients in ICU.

SSG13-06 Classification of Glioblastoma Using Machine Learning and Delta-Radiomic Signature Derived from Dynamic Susceptibility Enhanced MRI

PURPOSE

Glioblastoma (GBM) is the most aggressive cancer with poor prognosis due to its heterogeneity. The purpose of this study is to improve the tissue characterization of these highly heterogeneous tumors using delta-radiomic signature of dynamic susceptibility contrast enhanced (DSC) MR images, which are commonly used to derive blood perfusion parameters to the tumor, with machine learning approaches.

METHOD AND MATERIALS

Multiparametric magnetic resonance (MR) images of 25 patients with histo-pathologically confirmed 13 high and 12 low grade GBM were taken using a standard brain tumor imaging protocol. All DSC images were registered to FLAIR images. The tumor contours from FLAIR images and its contralateral regions of the normal tissue were used to extract delta-radiomic features from each DSC image over the entire volume of DSC time course images before applying feature selection methods. The most informative and non-redundant features (signature) were selected to train a random forest to differentiate high-grade (HG) and low-grade (LG) tumors while feature correlation limits were applied to remove redundancies. Then a leave-one-out cross-validation random forest was applied to the dataset to classify GBMs. To evaluate the performance of our proposed classification method, overall prediction accuracy, confidence, sensitivity and specificity were calculated.

RESULTS

Analysis of the predictions showed that our method consistently predicted the tumor grade of 24 out of 25 patients correctly (0.96). Based on the leave-one-out cross-validation, the mean prediction accuracy was 0.95±0.10 for HG and 0.85±0.25 for LG. The area under the receiver operating characteristic curve (AUC) was 0.94.

CONCLUSION

Our method performed well in classifying high and low grade GBMs based on the DSC MRI data. This study shows that delta-radiomic features of DSC MRI are correlated with GBM grades and may be use to improve imaging characterizing of gliomas. The performance of our method in interrogating DSC MRI data will be explored further using combined spatial and temporal delta-radiomic features.

CLINICAL RELEVANCE/APPLICATION

This study explores the new computational approach of delta-radiomic signature and machine learning to extract additional information from clinically applied DSC MR images to better classify GBMs.

SSG13-07 U-Net-Based Deep-Learning Bladder Segmentation in CT Urography

PURPOSE

To develop a U-Net based deep learning approach (U-DL) for bladder segmentation in CT urography (CTU) as a critical component for computer-aided diagnosis (CAD) of bladder cancer and treatment planning.

METHOD AND MATERIALS

Bladder segmentation in CTU remains a challenge because the bladder often contains regions filled with intravenous contrast and without contrast. We previously developed a bladder segmentation method using deep-learning convolution neural network (DL-CNN) and level sets within an user-input bounding box. However, some cases with poor image quality or with advanced bladder cancer spreading into the neighboring organs caused inaccurate segmentation. We have newly developed an automated U-DL method to identify the bladder boundary in CTU cases. The entire CTU slice containing bladder is used as input to the U-DL without the need for a bounding box. The output of U-DL is the corresponding bladder likelihood mask of the slice. No level set is used as a post-processing step. We trained the U-DL with a mini-batched stochastic gradient descent algorithm by minimizing a binary cross-entropy cost function using 7629 bladder slices from 81 CTU cases. The segmentation performance was evaluated using 92 independent test cases. 3D hand-segmented contours were obtained as reference standard for all cases. The segmentation accuracy was evaluated relative to the reference standard in terms of the average volume intersection ratio (AVI), average percent volume error (AVE), average absolute volume error (AAVE), average minimum distance (AMD), and the Jaccard index (JI).

RESULTS

For the independent test set, the AVI, AVE, AAVE, AMD, and JI for segmentation with U-DL were 93.0±9.8%, -3.0±13.9%, 8.9%±11.1%, 2.7±2.0 mm, 85.1%±10.9%, respectively. With DL-CNN and level sets, the corresponding values were 81.9%±12.1%, 10.2%±16.2%, 14.0%±13.0%, 3.6±2.0 mm, and 76.2%±11.8%, respectively. The improvement for all measures were statistically significant ($p<0.001$).

CONCLUSION

Compared to the previous method using DL-CNN and level sets, the U-DL is more accurate and does not depend on an user-input bounding box. Further work is underway to improve the U-DL as a fully automated method for segmentation of the bladder.

CLINICAL RELEVANCE/APPLICATION

Bladder segmentation is a crucial step for detection of bladder cancer and wall thickening in CAD and for treatment planning. This study developed a highly accurate method for bladder segmentation.

SSG13-08 Automated Detection of Hemorrhage and Fracture Regions in Head and Neck CT of the Trauma Patient in Emergency Rooms Using 3D Convolutional Neural Networks with Strong and Weak Labels

PURPOSE

To purpose and validate detection of hemorrhage and fracture using 3D convolutional neural network (CNN) with weak supervision in head and neck CT of brain trauma patient in emergency rooms.

METHOD AND MATERIALS

Brain CT images were acquired from 1785 healthy subjects and 2661 patients including 2451 and 1122 patients with hemorrhage including EDH, ICH and SDH and fracture, respectively. Weakly labeled data could lead to training failure due to high complexity and dimensionality problems. To solve of this problem, we used additional 169 patient's data with information of areas of fracture and hemorrhage were labeled. Using this hard labeled data, 3D patch images were extracted and trained before training weak supervision. After that, the network was fine-tuned using weak supervision with a relatively large amount of data. 3D CNN architecture was designed based on VGGNet-16 and global average pooling was performed before the prediction layer to extract the class activation map. Two independent networks were used to train and detect hemorrhages and fractures individually and evaluated in terms of accuracy, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV).

RESULTS

Our proposed method performance for hemorrhage detection showed 87.7%, 87.7%, and 87.6% and fracture detection showed 80.5%, 69.5%, and 87.8% for accuracy, sensitivity, and specificity. In addition, PPV and NPV of hemorrhage detection and fracture detection were 91.5%, 82.5% and 79.0%, 81.3%, respectively.

CONCLUSION

We proposed fully automated detection system using deep learning networks for brain injury patients in emergency rooms. The system helps to radiologists and physicians in emergency rooms reducing the diagnosis time and human errors. The automated detection system could be applied in various kinds of other abnormal detection with strong and week labels.

CLINICAL RELEVANCE/APPLICATION

This study could be used for CAD on hemorrhage and fracture in head and neck CT of brain trauma patient in emergency rooms.

SSG13-09 Quantitative MRI Radiomics in the Task of Distinguishing Between Malignant and Benign Breast Lesions in a Large Clinical Dataset from China

yuji710@uchicago.edu

PURPOSE

To evaluate the potential of quantitative MRI radiomics in the task of distinguishing between malignant and benign breast lesions in a large clinical dataset from China.

METHOD AND MATERIALS

Our research involved a clinical DCE-MRI database of 600 breast cases retrospectively acquired under a HIPAA-compliant with a waiver of consent IRB protocol. The average ages of the 300 benign and 300 malignant patients were 41.8 and 47.2 years with a standard deviation of 9.5 and 9.6 years, respectively. Characteristics of the breast cancers included clinical and histopathologic findings on axillary lymph nodes and tumors. Once each lesion was indicated to our radiomics workstation, the machine learning algorithm automatically segmented and extracted radiomic features on the primary lesion, including those from six categories: size, shape, morphology, enhancement texture, kinetics, and enhancement-variance kinetics. The selected feature subset was input to a Bayesian artificial neural network (BANN) classifier and underwent leave-one-case-out cross validation. Area under the receiver operating characteristic (ROC) curve (AUC) served as the figure of merit in the task of distinguishing between malignant and benign breast lesions.

RESULTS

In the task of distinguishing between malignant and benign breast lesions, the analyses of each radiomic feature demonstrated AUC values ranging from 0.53 (se = 0.02) to 0.78 (se = 0.02). A subset of features that characterize lesion irregularity, margin sharpness, textural and kinetics were selected. The resulting radiomic lesion signature from the BANN classifier yielded an AUC value of 0.88 (se = 0.01).

CONCLUSION

Quantitative MRI radiomics demonstrated promising classification performance in distinguishing between malignant and benign breast lesions in a large clinical dataset from China.

CLINICAL RELEVANCE/APPLICATION

Our computerized radiomic analysis method has potential to aid clinicians in improving breast cancer diagnosis and patient management.

PURPOSE

To detect vasa vasorum (VV) proliferation in arterial walls as an early marker of atherosclerosis using a whole-body photon counting detector (PCD) CT system.

METHOD AND MATERIALS

A swine carotid model of enhanced vasa vasorum (the micro vessels in artery walls) was developed in an anesthetized animal, by injecting autologous blood into the left carotid wall in multiple locations caudal to the bifurcation to mimic early stage atherosclerosis. The right carotid artery (control) was exposed but was not injected. The animal was allowed to recover, and six weeks later re-anesthetized and scanned using the PCD-CT system. Four locations caudal to the carotid bifurcation were scanned using the ultra-high resolution (UHR) PCD-CT acquisition mode and a 40mL contrast bolus (Omnipaque) followed by a 30mL saline chaser. Axial acquisitions (140kV, 342 mAs) were performed at 20 time points (1s rotation, 3s cycle time) allowing CT number measurements in arterial lumen and wall for peak enhancement and recirculation phases. The PCD-CT energy thresholds were set to be 30 and 70 keV. PCD-CT images were reconstructed using a quantitative sharp kernel(Q65). To reduce image noise, a multi-energy non-local means denoising algorithm was applied to the PCD-CT images. Arterial lumen-wall boundaries in the 30-140 keV images were identified using half-max CT number thresholding, and wall CT number enhancement was calculated using an annular ROI placed in the segmented arterial wall. The animal model of increased VV was validated using microfil-enhanced micro-CT (μCT) of excised carotids from the same animal.

RESULTS

Baseline corrected wall-lumen ratio integrated over the arterial recirculation phase showed a significantly higher value ($p = 0.0036$, unpaired t-test) for the left common carotid with enhanced vasa vasorum measured over a length of 22.5mm. Images from contrast-enhanced μCT showed VV proliferation in the excised left carotid, while the right carotid showed normal VV density.

CONCLUSION

We have demonstrated in vivo quantification of vasa vasorum proliferation in the carotid arteries of an animal model using contrast-enhanced PCD-CT. The findings were compared to ex vivo μCT of the carotids.

CLINICAL RELEVANCE/APPLICATION

Vasa vasorum proliferation precedes atherosclerosis and its detection could enable early diagnosis prior to irreversible consequences occur from vulnerable plauque, stenosis, infarction or stroke.

SSG14-03 High-Pitch Coronary CT Angiography in Revolution CT During Free Breathing versus Breath Holding in Patients with Unlimited Heart Rates

Tuesday, Nov. 27 10:50AM - 11:00AM Room: S405AB

PURPOSE

To explore the feasibility of coronary CT angiography (CCTA) using free breathing and evaluate the image quality CCTA in free breathing patients when compared to breath holding patients.

METHOD AND MATERIALS

60 patients with suspected coronary heart disease were randomly divided into two groups for CCTA scans: group A (n=30) were performed during breath-holding ,and the remaining 30 during free-breathing (group B).No heart rate control was performed before examination. The heart rate during planning was 57-113bpm in group A and 48-124bpm in group B .The basic information for the two groups was statistically the same.A coefficient of 25 mgl/kg/s was applied for all patients.CT value in Aortic sinus (AS), right coronary artery (RCA), left anterior descending (LAD), left circumflex (LCX), and pericardial fat and standard deviation (SD) in AS and fat were measured. Signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) for AS were calculated. We compared the differences in the heart rates during the planning and scanning period between two methods.Image quality of every coronary artery segment according to the American Heart Association 15-segment model with at least 1.0mm diameter was evaluated using 5-point grading scales(1: non diagnostic-5:excellent).Two experienced Radiologists also independently reviewed image quality of each coronary artery segment.

RESULTS

There was no statistical difference between the demographic data of the two groups. The subjective image quality scores for coronary artery image were 4.49±0.41(A) and 4.33±0.36(B).With breath-holding,91.7% of the coronary artery segments were evaluable with image quality scores of 4 and 5 compared to 89.5% with free breathing group($P>0.05$).The CT Value in AS ,SNR,CNR with RCA were significantly($P<0.05$) lower with group B,But CT numbers in LAD, LCX, RCA, as well as CNR between the two groups were not statistically different ($P>0.05$). The mean difference between the heart rates before and during scanning for group A was(1.74±1.86) bpm,and group B was (1.30±1.25) bpm,the two groups were not statistically different ($P>0.05$).

CONCLUSION

Free-breathing CCTA is feasible using 256-MDCT scanner without heart rate control, and aquire high quality image .

CLINICAL RELEVANCE/APPLICATION

Free-breathing CCTA is feasible using 256-MDCT scanner without heart rate control, and aquire high quality image .

SSG14-04 Early Investigation on CT Thermometry as a Tool to Monitor the Ablation Zone During Thermal Ablation Therapy

Tuesday, Nov. 27 11:00AM - 11:10AM Room: S405AB

PURPOSE

Percutaneous thermal ablation, such as microwave or radiofrequency ablation, is a clinical treatment for cancer that utilizes directed heating to induce cell death. Currently, there is no accurate way to evaluate the ablation zone, which can lead to incomplete ablation and thereby precipitate local recurrence of cancer. Since temperature affects mass density and since CT can measure changes in mass density, CT could be used to monitor the ablation zone. In this study, we test the hypothesis that a reliable, clinically significant decrease in attenuation can be seen in water heated from body temperature (36°C) to the temperature at which cell death occurs (above 55°C).

METHOD AND MATERIALS

Four bottles of water stacked in a 2 x 2 arrangement were heated to 75°C and then passively cooled to 30°C. The temperature within each bottle was monitored using independent thermometers (1°C accuracy). CT scans (120 kV, routine abdominal protocol) were taken after every 2°C drop until the desired temperature range was covered. A representative central slice passing through the four bottles was chosen. The mean attenuation coefficient in an 81 x 81 region-of-interest was evaluated within each bottle and plotted against temperature at time of acquisition.

RESULTS

At 73°C (the temperature measured during the initial CT scan), the attenuation of water was -24.6 ± 0.4 Hounsfield Units (HU). As the water cooled to 33°C (the temperature measured during the last scan), the attenuation increased to -5.0 ± 0.6 HU. The measurements were consistent across all 4 bottles. A linear model was fitted to all measurements (R^2 = 0.98). The model demonstrates an 11.52 HU change between 36°C and 60°C (95% confidence interval: [11.21-11.84], based on the Student distribution with 88 degrees of freedom).

CONCLUSION

Our study shows that there is a measurable decrease in CT attenuation between body temperature and 55°C, the temperature at which cell death occurs. This observed 11.5 HU change in attenuation can be clinically differentiated by radiologists at a reasonable radiation dose, indicating that parenchymal changes due to heating could be measured using CT.

CLINICAL RELEVANCE/APPLICATION

In thermal ablation, directed heating is used to treat pathology, especially malignancy. Reliable evaluation of the ablation zone using CT thermometry will allow more accurate cancer treatment.

SSG14-05 Effectiveness of Metal Artefact Reduction Algorithm in a New Generation Spectral CT

PURPOSE

The purpose of this study was to quantify the effectiveness of metal artefact reduction (MAR) algorithm in restoring the CT image quality with the new generation spectral CT scanner, and compared the results with those of an older generation CT scanner

METHOD AND MATERIALS

We retrospectively reviewed clinical data of twelve patients with pedicle screw fixation of fractured vertebrae or degenerated intervertebral disc. Institutional review committee approval and written informed consents from patients were obtained. All patients underwent CT scan during the first hospital admission and three weeks thereafter to evaluate the position of the pedicle screws. The initial CT examination was carried out using GE Discovery CT750 HD with 80/140kVp, 0.5s rotation and 0.986 pitch. The follow-up scan was performed at 0.5s rotation and 0.992 pitch using a new generation spectral CT (Revolution CT, GE Healthcare). Virtual monochromatic images (VMIs) were reconstructed at energy levels of 63, 68, 74, 88, and 105 keV. Artefact index (AI=v(Ns2-Nm2) was assessed by region of interest (ROI) measurements in position of the strongest artefact (Ns) and in a muscle structure without artefact (Nm) (noise in HU units). The subjective image quality was assessed by two experienced radiologists independently. The CTDIvol and dose length product (DLP) were recorded. All quantitative analysis was based on the mean value of parameter calculated from five VMIs.

RESULTS

Metal artefact index and radiation dose was significantly reduced in the new generation spectral CT (AI 18.27±7.09, CTDI 11.89±0.89, DLP 212.50±36.96) compared with that in older generation CT (AI 51.98±28.77, CTDI 17.51±1.63,DLP 276.69±42.11, $p<0.05$ for all). There was high agreement between two radiologists (kappa=0.682). Subjective image quality analysis showed significantly higher score at new generation CT scanner (3.82±0.68,3.85±0.66) than older generation CT scanner (2.12±0.76), (2.00±0.74).

CONCLUSION

The MAR algorithm in the new generation spectral CT allows for a significant reduction of metal artefacts and improved subjective image quality in patients with pedicle screw.

CLINICAL RELEVANCE/APPLICATION

Pedicle screw with high atomic number are widely used in orthopedic surgery and can produce severe metal artefact. The present study demonstrated that MAR algorithm in a new generation spectral CT was effective in reducing artefacts arising from pedicle screw.

SSG14-07 Improvement of Image quality in Low-Dose Computed Tomography Using a Deep Learning Based Denoising Algorithm

PURPOSE

To assess the image quality of low dose (LD) computed tomography (CT) using a deep learning based denoising algorithm (DLA) compared with filtered back projection (FBP) and advanced modeled iterative reconstruction (ADMIRE).

METHOD AND MATERIALS

Our institutional review board approved this retrospective study. A total of 50 patients underwent routine dose (RD) abdominal CT using FBP. CT images at 50%, 25%, and 13% dose levels of RD were simulated from RD CT images and reconstructed using FBP. We trained the DLA using the simulated LD CT images as input data and the RD CT images as the ground truth. To assess the image quality, we included five patients who underwent abdominal LD CT and additionally performed CT scan for the CTP 528 module of Catphan. CT images were reconstructed using FBP and ADMIRE (LD-FBP and LD-ADMIRE images). LD-FBP images were processed using DLA (LD-DLA images). We compared the mean image noise levels of LD-DLA, LD-ADMIRE and LD-FBA images in the liver, subcutaneous fat, paraspinal muscles and aorta drawing elliptical region-of-interests. Modulation transfer function (MTF) was measured at the images of CTP 528 module to assess the spatial resolution.

RESULTS

Mean image noises in LD-DLA images were significantly lower than LD-FBP images ($p<0.05$ for all) and similar compared with LD-ADMIRE images ($p>0.05$ for all). MTFs (mm^{-1}) of 10% contrast were 0.629, 0.629 and 0.635 in LD-DLA, LD-ADMIRE and LD-FBP images, respectively.

CONCLUSION

The LD-DLA images showed the less noise than LD-FBP images and comparable noise to LD-ADMIRE images while preserving the spatial resolution.

CLINICAL RELEVANCE/APPLICATION

Deep learning based denoising algorithm could improve the image quality of low dose computed tomography and be a new way to reduce radiation dose.

SSG14-08 Potential Application of Photon Counting CT in Cerebrovascular Imaging

Tuesday, Nov. 27 11:40AM - 11:50AM Room: S405AB

Participants

Ran Zhang, PhD, Madison, WI (*Abstract Co-Author*) Nothing to Disclose
Mang Feng, Madison, WI (*Abstract Co-Author*) Nothing to Disclose
Xu Ji, Madison, WI (*Abstract Co-Author*) Nothing to Disclose
Guang-Hong Chen, PhD, Madison, WI (*Abstract Co-Author*) Research funded, General Electric Company Research funded, Siemens AG
Ke Li, PhD, Madison, WI (*Abstract Co-Author*) Nothing to Disclose

PURPOSE

The goal of this work was to study the potential benefit of photon counting CT (PCCT) in imaging the cerebral vasculature. The scientific rationale was that compared with the current cerebral CT angiography (CCTA) technology, PCCT could provide better performance for cerebrovascular imaging tasks due to 1) improved energy weighting scheme applied to the photon signal and 2) significantly relaxed noise-spatial resolution tradeoff offered by the photon counting detector (PCD).

METHOD AND MATERIALS

An in-house experimental PCCT was constructed using a 51 cm CdTe-based PCD with a native pixel size of 100 μm. A customized angiographic CT head phantom containing contrast-enhanced healthy cerebral artery models (diameters ranging from 0.5 to 4.0 mm) was scanned by both the PCCT and a clinical MDCT with a clinical CCTA protocol. Radiation dose, beam collimation (20 mm), kV (100), reconstruction pixel size (0.4 mm) and slice thickness (1.25 mm) were matched between the two systems. MIP images were generated based on the instruction of the clinical CCTA protocol. CNR was measured at both proximal and distal branches of ICA and MCA. In addition, axial- and z-MTFs were measured for the two CT systems.

RESULTS

The CTDIvol and effective dose of the two systems were matched at 35 mGy and 1.23 mSv, respectively. Based on the measured axial MTF of MDCT, the reconstruction kernel of PCCT was adjusted until the axial spatial resolution of the two CT systems was matched; under this condition, the CNR of the proximal arteries (diameter 4.0 mm) was 44.7±12.2 in MDCT and was 87.5±22 ($p=0.0003$) in PCCT. For the distal and smaller artery branches (0.5 mm) the CNR was 11.3±6.3 for CCTA and 17.3±6.1 for PCCT ($p=0.013$). 10% MTF along z was 1.1 lp/mm for MDCT and 2.1 lp/mm for PCCT. The MDCT MIP demonstrated artifactural stenosis in a healthy angular artery due to partial volume effect; in contrast, the PCCT MIP provided more accurate and clearer rendering of all the arteries evaluated.

CONCLUSION

With matched dose and axial spatial resolution, PCCT provides higher vessel CNR, better z resolution, and reduced partial volume artifact, which suggests its promising application in cerebrovascular imaging.

CLINICAL RELEVANCE/APPLICATION

PCCT has the potential to address two major challenges in clinical CCTA: 1) limited CNR and spatial resolution of MDCT in imaging small or partially enhanced vessels; 2) distortions of true artery information due to image artifacts.
